How Hidden Local Government Debt Shapes Shadow Banking Competition

Evidence from Wealth Management in China

Kevin Zheyuan Cui[1] Tao Shen[2] Tianqi Zhi[2]

October 2026

Abstract

Using granular holdings data on China's RMB 33 trillion market for wealth-management products operated by banks or their subsidiaries, we study how government support for borrowers shapes competition in shadow banking. Smaller banks sought an edge over larger rivals by reaching for yield in home-province bonds issued by local government financing vehicles (LGFVs). The 2023 debt resolution initiative strengthened expected support for LGFVs and compressed their bond spreads. The estimated product-return premium associated with home LGFV bonds fell by 69%. Larger local banks expanded into higher-yielding, LGFV-linked private credit, while smaller banks substituted little and lost ground in relative product returns and wealth-management balances. Our model explains this unequal adjustment through fixed contracting costs that make investment scale important. Government support for borrowers can thus erode smaller banks' competitive edge and shift shadow banking toward larger intermediaries and more opaque credit.

JEL classification: G11, G21, G23, H63, H74

Keywords: local credit, bank competition, shadow banking, wealth-management products, debt resolution, local government financing vehicles, private credit

1 Introduction

Borrowing by local government financing vehicles (LGFVs), widely described as China's hidden local government debt, fueled the expansion of its shadow banking system. After the 2009 fiscal stimulus, LGFVs refinanced maturing bank loans through bonds and shadow-banking channels (Chen et al. 2020). Wealth-management products (WMPs), which pool savers' money outside banks' own balance sheets, became central to this system (Acharya et al. 2025). At the end of 2025, WMPs held RMB 33 trillion, nearly a quarter of China's GDP, for about 143 million investors, almost all of them individuals.[1] WMPs also held an estimated 28.1% of outstanding LGFV bonds at the end of 2024 (Figure A4). Much of the literature examines how shadow banking finances LGFVs. Using granular WMP portfolio data, we study the other side of this relationship: how LGFV bonds shape competition for household savings within shadow banking.

Because national and other larger banks have stronger reputations with investors, product performance is an important way for smaller local banks to compete for savers. These banks competed by holding higher-yielding LGFV bonds from their home provinces in products that restrict withdrawals. China's 2023 local-government debt resolution program undercut this strategy. By allowing provinces to issue special refinancing bonds to repay selected LGFV obligations, the program strengthened expected support for LGFVs and compressed their bond spreads. After the program, the estimated extra return that products earned from home LGFV bonds fell by 69%. Larger local banks replaced part of the lost yield with higher-yielding, LGFV-linked private credit, whose fixed contracting costs favor scale. Smaller banks substituted little, and their product returns and WMP balances declined relative to those of larger rivals. Government support for local borrowers can therefore cost smaller banks the yield on which they compete and move shadow banking toward larger banks and less transparent credit.

[1] Industry statistics are from the Banking Wealth Management Registration and Depository Center's annual market reports (2025; 2026), referred to below as the annual WMP market reports. China's 2025 GDP of RMB 140.2 trillion is the National Bureau of Statistics' preliminary estimate.

In the WMP market, large state-owned and nationwide joint-stock banks, which we call national banks, compete with local banks serving provincial, city, and rural markets. Offering higher returns requires higher-yielding investments, and those accessible to WMPs are scarce. Products can hold government and policy-bank bonds, deposits, negotiable certificates of deposit, and corporate debt, but safer instruments offer limited spreads and China's public high-yield bond market is narrow (Schipke et al. 2019). LGFV bonds help fill this gap. All eligible investors can buy them, and local banks can draw on familiarity with the borrowers. Private credit (PC), classified in China as non-standard debt, can finance the same borrowers at higher yields through less transparent, nontraded claims such as trust loans and financing through asset-management plans. Unlike buying a marketable bond, arranging these investments entails sourcing, evaluation, and contracting costs. These costs are the source of the scale advantage in our model.

We link quarterly holdings of 60,396 WMPs from 171 banks over 2022Q1–2025Q3 to product returns, investor flows, issuer credit events, and bank-level WMP balances. These data let us compare local and national banks, and local banks of different sizes, before and after debt resolution. Our evidence proceeds in three steps.

First, we document local banks' investment strategy before the program. LGFV bonds accounted for 43.1% of the bonds and private credit held by local banks' WMPs, compared with 12.6% at national banks.[2] Local banks concentrated their LGFV bond holdings in their headquarters provinces, more than the size of those provinces' bond markets would predict, and we refer to these holdings as home LGFV bonds. Across all banks, smaller institutions held larger home LGFV shares. Local banks competed by combining this home investment with product design. Periodic-open and closed-end products, which restrict withdrawals and give banks more room to hold assets that are hard to sell quickly, accounted for 80.2% of their product assets, compared with 47.3% at national banks. In daily-open products, local

[2]Shares are by holding value over 2022Q1–2023Q3. The denominator is identified bonds and private credit with known borrower locations, excluding central-government, central-bank, and policy-bank obligations. It is not total WMP assets. Section 3.1 defines it, and Internet Appendix D.8 compares it with bond-only shares.

banks invested no more at home than national banks. In products that restrict withdrawals, the local–national gap in home investment, measured relative to provincial market weights, was 20 percentage points larger than in daily-open products.

These home holdings mattered commercially. Before the program, products with more home LGFV bonds earned higher returns, and home LGFV bonds carried the largest estimated return premium among the asset categories we examine, exceeding that of LGFV bonds from other provinces. Higher returns in turn attracted savings. Within risk and withdrawal categories, top-return-quintile products attracted subsequent net inflows exceeding those of bottom-quintile products by 12.2% of beginning assets. Home bonds thus helped local banks compete for savings.

Why do local banks seek yield at home rather than elsewhere? Pricing and distress tests point to both local information and support for local borrowers. Among otherwise similar LGFV bonds, a larger share of the issue bought by WMPs of banks elsewhere in the issuer's province is associated with less overpricing at issuance relative to public secondary-market valuations. These buyers obtain better terms, consistent with informed purchasing.[3] Banks in the issuer's own city show the opposite pricing pattern: their greater participation accompanies higher issue prices and lower yields, which lowers the borrower's financing cost. However, same-city participation is also associated with fewer subsequent issuer credit events, conditional on observed initial risk. Local banks thus appear to combine informed selection with some support for local borrowers while reaching for yield.

Second, we show that debt resolution changed the relative returns available on bonds and private credit. Average LGFV issuance spreads over Treasury yields fell from about 200 basis points before implementation to 97 afterward, with greater compression in provinces with more refinancing. Private credit retained more yield: between 2023Q2 and 2024Q4, its

[3]WMP holdings first disclosed in the issue quarter proxy for primary-market purchases. Order-level allocations are not observed.

contractual yield advantage over LGFV bonds widened from 2.0 to 3.2 percentage points.[4] The contrast also appears in WMP performance. For a product with 20 percentage points more of its portfolio in home LGFV bonds, the estimated extra annual return fell from about 21 to 7 basis points, a 69% decline and the largest among the asset categories, while home private credit retained a positive premium. As home LGFV bonds lost their return advantage, local banks reduced their holdings more than other buyers of the same cities' bonds, and the retreat was greater at institutions initially more tilted toward home investments. Because other accessible investments offered little yield, replacing the lost bond yield depended on banks' ability to use private credit.

Third, we show that local banks differed sharply in what replaced their home bonds. Before the program, private credit was concentrated at national banks, which held 82.7% of the private credit identified in WMP portfolios, mostly outside their headquarters provinces. After resolution, larger local banks expanded its use at home. The largest third of local banks increased home private credit from 7.45% to 18.26% of the bonds and private credit in their WMPs, more than offsetting their reduction in home bonds, while the smallest third kept this share below 1%. The difference persists after accounting for initial portfolios and common provincial conditions. Most expansion remained within the LGFV sector: larger banks changed financing instruments while continuing to finance local LGFVs. Smaller banks continued launching new products but rarely included private credit in them, so their limited substitution does not merely reflect legacy portfolios.

These investment differences predict which banks lost more return and raised less money from savers. We relate each bank's change in WMP returns to its initial home LGFV exposure and its later expansion in home private credit, controlling for initial size and private-credit holdings. Ten percentage points more initial exposure predicts about 16 basis points more annualized return decline, whereas a ten-point larger expansion is associated with about 11

[4]In the financing-amount-weighted series, private-credit yields fell from 6.6% to 5.9%, compared with 4.6% to 2.7% for bonds (Figure 2). Comparing the same legal borrower and financing month, with maturity controls, also shows a widening gap: from 1.9 percentage points in 2023Q2 to 2.9 in 2024Q4 (Figure 3).

basis points less decline. The same pattern appears in fundraising through newly launched WMPs.[5] Ten points more initial home LGFV exposure predicts 15.3% lower new-product balances, while a ten-point larger private-credit expansion is associated with 14.6% higher balances, relative to pre-program differences and conditional on initial size and private-credit holdings. With both investment measures included, the coefficient on bank size is statistically insignificant in both regressions.

Smaller local banks combined substantial home LGFV reliance with little private-credit substitution, so both investment differences line up with bank size. Comparing banks by size alone, without holding these two investment measures fixed, shows how smaller banks fared overall. After implementation, the annual product-return gap between a local bank and one twice as large widened by about 10 basis points, and the larger bank's total WMP balances grew about 11% more. The size comparisons show that smaller banks lost ground, and the regressions above connect these losses to the bond yield they relied on and their limited use of private credit.

Our model connects the incentive to offer high returns with the ability to replace lost yield. Reputation attracts cautious savers to larger banks, leaving smaller banks to compete more heavily on yield. Investing in private credit requires a fixed cost that a larger investor base can cover through additional fee income. Debt resolution raises the value of private credit by compressing bond yields, and larger banks then find the substitute worthwhile even though smaller banks need it more. Banks that cannot cover the cost lose more of the return advantage with which they compete.

These findings reveal a less-explored side of the two-way relationship between LGFV borrowing and shadow banking. Shadow banks finance local public investment, but the yield available on LGFV debt also shapes how they compete for savings. Policies toward local government debt therefore affect not only public finances but also competition in shadow banking to attract household savings and the way those savings are invested.

[5]We proxy funds raised by total balances in products launched in a quarter, measured at the end of the following quarter. Section 5.5 gives the construction.

Our paper contributes to three strands of the literature. First, we connect shadow banks' role in financing local public investment to their competition for savings. Existing work traces off-budget fiscal expansion through LGFVs (Bai et al. 2016), the refinancing of stimulus loans through bonds and shadow banking (Chen et al. 2020), and the crowding out of private investment (Huang et al. 2020). Related studies show how deposit competition (Acharya et al. 2025), liquidity rules (Hachem and Song 2021), and monetary tightening (Chen et al. 2018) encouraged banks' shadow-banking activities. Implicit guarantees also shaped the pricing and funding of trust products and WMPs (Allen et al. 2023; Huang et al. 2023).

More broadly, research explains shadow banking through demand for claims perceived as safe (Gennaioli et al. 2013), regulation and technology (Buchak et al. 2018), and competition with insured deposits (Xiao 2020). Low interest rates can also change funds' product choices and industry structure (Di Maggio and Kacperczyk 2017). We show that investment opportunities shape competition among shadow banks. LGFV bond yield helped smaller banks offset weaker franchises, while the scale required to replace that yield left them at a disadvantage once debt resolution compressed it.

Second, we connect local specialization to competition on returns. Distance and organizational form shape lenders' use of borrower information (Petersen and Rajan 2002; Degryse and Ongena 2005; Hauswald and Marquez 2006; Agarwal and Hauswald 2010; Stein 2002; Berger et al. 2005). Geographic and industry concentration are associated with investment performance (Coval and Moskowitz 2001; Kacperczyk et al. 2005; Loutskina and Strahan 2011), while lending specialization makes credit relationships difficult to substitute (Paravisini et al. 2023). Performance-sensitive flows and redemption risk shape asset managers' incentives (Sirri and Tufano 1998; Chen et al. 2010; Goldstein et al. 2017), and competition (La Spada 2018; Choi and Kronlund 2018) and regulatory constraints (Becker and Ivashina 2015) can encourage reaching for yield. We show how familiar local bonds helped smaller banks compete on returns, and why replacing that yield required greater scale.

Third, we study how borrower support affects financial intermediaries. Governments influence credit allocation (Sapienza 2004; Khwaja and Mian 2005) and, under fiscal stress, banks' holdings of government debt (Becker and Ivashina 2018; Ongena et al. 2019). In China, creditor political power affects selective defaults (Gao et al. 2021), and expected government support shapes the pricing gap between state-owned and private borrowers (Geng and Pan 2024). Geng et al. (2025) trace the government-led LGFV credit cycle and show that debt resolution narrows local banks' subordinated-bond spreads while reducing profitability and market shares at banks in riskier cities. Our contribution is to identify the investments through which this borrower support changes competition in banks' off-balance-sheet savings businesses. Granular WMP holdings reveal both the source of the initial return advantage, home LGFV bonds, and the higher-yielding substitute increasingly used by larger local banks. The distinctive implication is that government support for borrowers can change not only intermediaries' performance but also the instruments through which they compete and supply credit.

Section 2 introduces the market, policy, and data. Section 3 documents local banks' investment strategy and product design, the strategy's contribution to returns and investor demand, and evidence on information and borrower support. Section 4 studies yield compression and bond retreat. Section 5 examines unequal substitution, returns, and fundraising through newly launched WMPs, followed by differences in overall WMP-business growth by bank size. Section 6 explains these findings with a model in which savers differ in risk aversion and private credit requires a fixed cost. Section 7 concludes.

2 Setting and Data

This section describes the WMP market and its place in household savings and shadow banking, the investments available to WMPs, the debt-resolution program, and the data we use.

2.1 Banks, products, and investment opportunities

A wealth-management product pools savers' money in a separately accounted investment portfolio run by a bank or its wealth-management subsidiary. For Chinese households, WMPs are a major alternative to bank deposits, and they form a central part of the country's shadow banking system (Acharya et al. 2025; Chen et al. 2020). Since the 2018 asset-management reform, products must report net asset values (NAVs) and cannot guarantee principal or returns.[6] Banks sell WMPs through branches and online platforms. National banks comprise large state-owned and nationwide joint-stock commercial banks, with extensive branch networks and nationwide name recognition. Local banks include provincial, city, and rural institutions. They compete for savings with national banks and with one another.

WMPs invest primarily in fixed-income and similar assets. Permitted investments include government and policy-bank bonds, deposits, negotiable certificates of deposit, and corporate debt.[7] Most readily accessible investments offer limited credit spreads, while the public high-yield corporate bond market is narrow (Schipke et al. 2019). Figure A1 shows the industry's asset mix, and Figure A2 traces its growth.

LGFV bonds provide one source of higher yield. LGFVs are state-owned companies that finance local infrastructure and public services. They borrow in their own names, separately from formal government debt. Repayment depends on project assets, local fiscal resources, and expected government support (Hendy et al. 2024; Yang and Jiang 2021). Favorable issuance review helped qualifying vehicles obtain bond financing.[8] In our pre-program sample, LGFV issuers were smaller and their bonds offered higher issuance yields than those of other issuers. Median FY2021 assets were RMB 28.4 billion, compared with RMB 35.3 billion for other nonfinancial issuers and RMB 52.9 billion for financial issuers (Table A3, Panel E).

[6] See the asset-management reform guidelines (2018).

[7] Article 35 of the commercial-bank WMP rules lists permitted investments (2018).

[8] The enterprise-bond review notice (2013) provided accelerated and simplified review for a qualifying urban investment company's first application when its debt-to-assets ratio was below 50%. Exchange-market corporate bonds and interbank corporate debt instruments follow separate review and registration frameworks (2021; 2015).

Average fixed-rate issuance yields were 4.26%, 3.03%, and 2.77%, respectively. The LGFV yield differences persist after controlling for issue characteristics and ratings (Table A14). All eligible investors can buy these bonds, but local banks can draw on lending, deposit, and payment relationships to assess familiar but opaque borrowers.

WMPs can also finance the same borrowers through private credit, classified by Chinese regulators as non-standard debt. These investments include identified trust loans, leasing receivables, and claims held through trust or asset-management plans. Unlike buying marketable bonds, investing in private credit requires arranging, documenting, and monitoring a contract without a continuously observable trading price. These activities entail costs even for a small investment. The same borrower can issue both bonds and private credit.

The WMP–LGFV bond link is economically important for both markets. At year-end 2024, we estimate that WMPs held about RMB 3.1 trillion in LGFV bonds, representing 10.2% of total WMP net assets and 28.1% of outstanding LGFV bonds (Figure A4). These industry totals are extrapolated from disclosed holdings, and Internet Appendix D.8 explains the calculation and its denominators.

2.2 Debt resolution and the linked data

The policy announcement of July 24, 2023, called for comprehensive local-debt resolution. Provinces began issuing special refinancing bonds in October, raising about RMB 1.4 trillion in 2023Q4 (Xinhua News Agency 2023; Wang 2023; Wong 2024). The proceeds repaid selected obligations as part of a broader program that also included loan restructuring and restrictions on new borrowing. These refinancing bonds are provincial-government obligations, distinct from the LGFV bonds held by WMPs. An expansion announced in November 2024 added RMB 6 trillion of debt-swap capacity for 2024–2026 (Ministry of Finance 2024). The program strengthened expected government support without formally guaranteeing every LGFV claim. The resulting spread compression can raise the prices of existing bonds while reducing the

yields available when banks reinvest. We date implementation to 2023Q4, or October in monthly tests.

We start from product-level WMP holdings in Wind, a Chinese financial database, and link them to NAVs, bond issuance, and borrower-side private credit disclosures from a commercial data vendor. The holdings data identify each product's largest disclosed positions at the individual-asset level.[9] Quarterly disclosures over 2022Q1–2025Q3 contain 2,279,252 holding-level records for 60,396 products, covering 253,484 product-quarters. The sample includes 171 banks headquartered in 30 provinces: 18 national banks (six state-owned and twelve joint-stock) and 153 local banks (100 provincial or city commercial banks and 53 rural banks). Tables A1–A3 define the variables and report sample coverage and descriptive statistics.

3 Local Credit and Competition for Savings

Local banks compete for savings against national banks with stronger reputations and broader distribution networks. Higher returns can offset that disadvantage. This section asks which investments provided the return advantage, whether it attracted savers, and why local banks sought it through familiar borrowers.

Our investment and performance outcomes concern banks' WMP businesses. Throughout, a bank's holdings and product returns refer to its WMPs, whether operated directly or through a wealth-management subsidiary. We assign each WMP its underlying bank's national or local category. An investment is home when its borrower is in that bank's headquarters province, so both national and local banks' WMPs can hold home and non-home assets.

Throughout the product regressions, i denotes a product, a its issuing bank or subsidiary, b the underlying bank (the parent bank in the tables), q a quarter, m a month, and p_b the bank's headquarters province. For monthly returns, we distinguish a product's separately priced

[9]The headline allocation and return-premium findings survive disclosure controls and alternative exposure denominators (Internet Appendix E.2).

NAV series, such as share classes. Log bank size$_b$ always refers to fixed FY2021 bank size, whereas log bank assets in the control rows varies over time. Controls contains the covariates listed for each specification. The indicator $\mathbb{1}\{\cdot\}$ equals one when the stated condition holds and zero otherwise.

3.1 Overall asset allocation

We first compare LGFV bonds with private credit, the two higher-yielding WMP investments central to the analysis. To place them on a common basis, we express each holding as a share of the combined value of identified bonds and private credit with known borrower locations, excluding central-government, central-bank, and policy-bank obligations. We call this denominator included debt holdings. It covers only this part of the WMP portfolio, not total WMP assets.[10]

The initial WMP portfolios differ sharply by bank type. LGFV bonds accounted for 43.1% of included debt holdings at local banks, compared with 12.6% at national banks, while private credit accounted for 9.3% and 24.1%, respectively (Table D1). Local banks' WMPs relied more on marketable LGFV bonds, whereas national banks' WMPs already made substantial use of private credit.

The bank-type comparison leaves open how these investments vary with size. We therefore estimate the initial size gradient across national and local banks:

$$\text{Asset share}_{iq} = \beta_S \,\text{Log bank size}_b + \gamma' \,\text{Controls}_{iq} + \alpha_q + u_{iq}. \tag{1}$$

Here the outcome is the total LGFV bond share or total private credit share, in percentage points of included debt holdings. Log bank size$_b$ is log FY2021 underlying-bank interest-bearing assets in RMB trillion, and products of a bank and its subsidiary share that measure.

[10] It excludes deposits, funds, and other assets, and it differs from total WMP net assets, the denominator of the 10.2% industry estimate in Section 2. Internet Appendix D.8 reconciles the samples and denominators, including bond-only shares, and Table A10 reports the broader disclosed portfolio.

A doubling increases Log bank size$_b$ by $\ln 2$. The ten variables in Controls$_{iq}$ are three product characteristics (size, risk rating from 1 to 5, and redemption terms), three bank characteristics (nonperforming-loan ratio, cost–income ratio, and net interest margin, in percent), and four home-city characteristics (GDP, GDP growth, LGFV debt/GDP, and urban income).[11] The coefficient β_S compares allocations across bank sizes, holding these characteristics and quarter conditions fixed.

Across national and local banks, smaller banks' WMPs allocate more to LGFV bonds and less to private credit (Table 1). For a bank twice as large, the estimated LGFV bond share is about 4.9 percentage points lower and the private credit share 4.7 points higher. The underlying coefficients are −7.13 and 6.83 points per log point of bank assets. Private credit is also scarce at the smallest local banks, where it accounts for only 1.1% of included debt holdings, compared with 11.4% at the largest third (Table D1, Panel B). Smaller banks therefore enter the program more dependent on marketable LGFV bonds and with little use of the privately arranged alternative.

3.2 Home-province allocation

The asset mix is only part of the specialization. Local banks also concentrate investment in their home provinces. Home LGFV bonds account for more than one-fifth of included debt holdings in every local-bank size group (Table D1, Panel B). Applying equation (1) to the home LGFV share, rather than the total LGFV share, gives a size coefficient of −5.46 percentage points per log point of bank assets (Table 1). Across all banks, a bank twice as large therefore has a home LGFV share about 3.8 points lower, or RMB 3.8 less in home LGFV bonds per RMB 100 of included debt holdings, holding the controls fixed. Most of the greater LGFV allocation at smaller banks is in their home provinces.

[11] The sample is 2022Q1–2023Q3. Category zeros remain, and shares are not benchmark-adjusted. Regressions weight by included debt value and cluster by underlying bank. Fixed size replaces contemporaneous bank assets, and quarter effects enter without bank effects or a local-bank indicator. Internet Appendix D.9 gives the sample and weighting definitions.

Large home holdings could reflect a large local bond market rather than a preference for nearby borrowers. To distinguish the two, we first measure geographic concentration within each asset class. For LGFV bonds, we divide the product's home LGFV holdings by all its LGFV holdings, then subtract the fraction of nationwide disclosed LGFV holdings issued by borrowers in that province. We call this difference within-category home bias. Its denominator is LGFV bonds alone, not the product's entire debt portfolio. The same calculation applies separately to other bonds and private credit. Over 2022Q1–2025Q3, we estimate

$$\begin{aligned}\text{Within-category home bias}_{iq}^{n} = \beta_n \, \mathbb{1}\{\text{Local bank}\}_b \\ + \gamma_n' \, \text{Controls}_{iq} + \alpha_q + \varepsilon_{iq}.\end{aligned} \tag{2}$$

Here n identifies the asset class. Zero within-category home bias means that, within that class, the product invests in its home province at the nationwide portfolio weight, and a positive value means it invests more at home. The local-bank indicator identifies products issued by local banks or their subsidiaries, so β_n measures their additional within-category home bias relative to national-bank products. Only products holding the asset class enter, since the within-class ratio is otherwise undefined.[12]

Local banks' WMPs invest disproportionately at home (Table 2). The LGFV coefficient of 0.3205 means that their within-category home bias is 32.0 percentage points greater than that of national-bank products. For every RMB 100 invested in LGFV bonds, this represents about RMB 32 more invested at home, relative to each province's nationwide portfolio weight and holding the controls fixed. The analogous differences are 16.1 points within other bonds and 48.9 points within private credit. Local banks' specialization is therefore geographic as well as a choice of asset class.

[12]Controls are the product's size, risk, withdrawal terms, disclosure count, and disclosure coverage, the bank's average product term and risk, its nonperforming loans, cost–income ratio, and net interest margin, and home-city GDP growth. Errors cluster by headquarters city–quarter. Internet Appendix D.9 defines both denominators.

Product design provides another way to see how local banks compete. Periodic-open and closed-end products account for 80.2% of their product assets, compared with 47.3% at national banks (Table A5). These products restrict withdrawals, giving banks more room to hold investments that are difficult to sell quickly. Daily-open products instead compete more directly on access to cash.

To connect withdrawal terms to investment, we need to know how much of the portfolio goes to home borrowers, not just where a category's holdings are located. We therefore change the denominator. For LGFV bonds, we now divide home LGFV holdings by all the product's included debt holdings, rather than by LGFV bonds alone. The benchmark changes accordingly: nationwide holdings of LGFV bonds from that province are divided by nationwide included debt holdings. Portfolio home overweight is the product's allocation minus this benchmark.[13] This portfolio-level measure captures both the amount invested in the asset class and its geographic concentration. We estimate

$$\begin{aligned}\text{Portfolio home overweight}_{iq}^{n} = \beta_1 \, \mathbb{1}\{\text{Local bank}\}_b \\ + \beta_2 \, \mathbb{1}\{\text{Restricted redemption}\}_i \\ + \beta_3 \, \mathbb{1}\{\text{Local bank}\}_b \times \mathbb{1}\{\text{Restricted redemption}\}_i \\ + \gamma' \, \text{Controls}_{iq} + \alpha_q + \varepsilon_{iq}.\end{aligned} \tag{3}$$

$\mathbb{1}\{\text{Restricted redemption}\}_i$ identifies products without daily withdrawals. Unlike within-category home bias, Portfolio home overweight$_{iq}^{n}$ is defined even when the product holds none of class n: its raw allocation is zero before subtracting the benchmark, so these products remain in the sample. The coefficient β_1 measures the local–national allocation gap among daily-

[13] For example, consider a WMP with RMB 100 in included debt holdings, including RMB 20 in LGFV bonds, of which RMB 10 is from home. Its within-LGFV home share is 50%, but its home LGFV allocation is 10% of included debt holdings. Each measure subtracts the matching nationwide benchmark. Neither denominator is total WMP assets.

open products, and β_3 measures how much wider that gap is among restricted-redemption products.[14]

Local banks invest more at home than national banks only in products that restrict withdrawals (Table A6). Among daily-open products, the local-bank coefficient is −6.3 percentage points when home investments are pooled across asset classes and 0.9 points (standard error 1.3) for LGFV bonds, so local banks invest no more at home than national banks. The interaction with restricted redemption is 20.0 percentage points for pooled home investment. Per RMB 100 of included debt holdings, the local–national gap in home investment above the nationwide benchmark is therefore RMB 20 larger among restricted-redemption products than among daily-open products, holding the controls fixed. Of this additional gap, RMB 7.7 is in LGFV bonds and RMB 7.8 in private credit. Local banks therefore compete through the combination of withdrawal restrictions and home investment, and they make greater use of both.

The geographic and product-design evidence shows how local banks differentiate their WMPs, pairing investment in home borrowers with withdrawal terms that accommodate less liquid holdings. For the smallest banks, substantial home LGFV positions coexist with little private credit and few accessible high-yield alternatives.

3.3 Local credit and product returns

These portfolios matter for competition only if their home LGFV bonds helped local banks offer higher returns. We compare returns across products with different allocations, distinguishing home LGFV bonds from bonds elsewhere and from private credit, while controlling for product, bank, and local characteristics. A single specification estimates both the pre-program premiums discussed here and their subsequent changes in Section 4.3. We relate

[14]The controls are those in equation (1), excluding redemption, which enters separately, and adding time-varying log bank assets. The sample is 2022Q1–2025Q3. Quarter effects enter, and errors cluster by bank city–quarter. Internet Appendix D.3 gives the construction.

monthly returns to holdings at the preceding quarter end:

$$\begin{aligned}\text{Monthly return}_{im} = {} & \beta' \,\text{Asset shares}_{i,h(m)} \\ & + \delta' \,\text{Asset shares}_{i,h(m)} \times \mathbb{1}\{\text{Post}\}_m \\ & + \gamma' \,\text{Controls}_{i,h(m)} + \lambda \,\mathbb{1}\{\text{Local bank}\}_b + \alpha_m + \varepsilon_{im}.\end{aligned} \tag{4}$$

The outcome Monthly return$_{im}$ is the change in log distribution-adjusted NAV, in basis points. In this specification i is a separately priced NAV series, assigned its product's holdings. The five fractions Asset shares$_{i,h(m)}$ are home LGFV bonds, home private credit, home other bonds, non-home LGFV bonds, and non-home private credit, relative to included debt holdings. Non-home other bonds are omitted. Holdings and controls are measured at the preceding quarter end $h(m)$, so June holdings explain July–September returns. Post starts in October 2023. Column 1 of Table 3 includes product controls, and column 2 adds bank and home-city controls on the same sample and is our baseline.[15]

Before implementation, Post equals zero, so β measures each asset's return premium relative to non-home other bonds. These are the coefficients we interpret here. The interactions δ allow the premiums to change afterward, and Section 4.3 examines those changes and the remaining premiums $\beta + \delta$. For a 20-percentage-point allocation replacing non-home other bonds, the annualized comparison is 12×0.20 times the coefficient (Table 3).

Home LGFV bonds provide the largest estimated pre-program return premium (Table 3). Reallocating 20 percentage points from non-home other bonds to home LGFV bonds is associated with about 21 annual basis points more product return, compared with about 7 basis points for LGFV bonds from other provinces. The raw monthly coefficients are 8.852

[15]The eleven controls add time-varying log bank assets to the ten controls in equation (1). The regression includes a local-bank indicator and month effects, with underlying-bank-clustered errors. It uses April 2022–December 2025 returns, excluding observations outside the 1st–99th percentile ranges of returns or trailing volatility. September 2025 holdings support October–December returns. The estimates measure conditional premiums in reported returns. Internet Appendix E examines measurement sensitivity.

and 3.041 per unit share. The home premium is almost three times the non-home premium, and their difference is statistically significant.[16]

Private credit also has a larger return premium at home: the same 20-point allocation corresponds to about 16 annual basis points for home claims and 7 for claims elsewhere, from raw coefficients of 6.765 and 2.776. Home other bonds contribute little, with a coefficient of 0.506. This pattern ties the higher returns to LGFV bonds and private credit rather than to home investment generally. Home LGFV bonds also have enough weight to matter: their initial mean allocation is 26% and the 90th percentile 72% (Table A3).

We also ask whether higher reported returns came with more frequent visible losses. Using the full-period specification in equation (D.10), we relate reported volatility and downside outcomes to benchmark-adjusted home LGFV exposure (portfolio home overweight in LGFV bonds), retaining the eleven controls, local-bank indicator, and month effects (Table A7). A 20-point exposure difference is associated with a 0.8-percentage-point lower probability of a negative month, against a 9.9% mean. Savers therefore observed relatively smooth performance alongside the higher returns.[17]

3.4 Performance and investor demand

We next ask whether better-performing WMPs attracted more savings. We rank products' prior-quarter returns within the same risk rating and withdrawal category, comparing products from both local and national banks. Following the performance–flow approach in Sirri and Tufano (1998) and La Spada (2018), we estimate

$$\begin{aligned}\text{Net flow}_{iq} = &\sum_{k=2}^{5} \beta_k \mathbb{1}\{\text{Return quintile}_{i,q-1} = k\} \\ &+ \gamma' \,\text{Controls}_{i,q-1} + \lambda\, \mathbb{1}\{\text{Local bank}\}_b + \alpha_{g(i,q-1),q} + \varepsilon_{iq}.\end{aligned} \tag{5}$$

[16]The pre-program home-minus-non-home LGFV contrast is 5.811 monthly basis points per unit share (bank-clustered SE 1.756, $p = 0.0012$), calculated from the same regression and its covariance matrix. At a 20-point allocation difference, the contrast is about 14 annual basis points.

[17]Exposures lag one quarter, and errors cluster by bank city–month. These outcomes measure fluctuations in reported NAVs. Internet Appendix D.6 defines the outcomes and specification.

The outcome Net flow$_{iq}$ is asset growth net of investment gains, as a percentage of beginning assets. Return quintile$_{i,q-1}$ is prior return quintile, with the bottom fifth omitted, and $g(i, q-1)$ identifies prior risk and withdrawal categories. Category–quarter effects hold common demand conditions fixed, and Controls$_{i,q-1}$ contains the lagged covariates listed below. The coefficient β_5 is the top–bottom flow difference.[18]

Flows increase across the performance ranks (Table A9). Top-quintile products receive subsequent net inflows 12.2% of beginning assets greater than bottom-quintile products, or RMB 12.2 million for a product initially holding RMB 100 million, and are 8.1 percentage points more likely to receive positive flows. Comparing products of banks in the same home province and quarter gives a similar 12.8% flow difference. This relationship between performance and inflows gives local banks a reason to seek the return premium associated with home LGFV bonds.

3.5 Local information and borrower support

Higher returns help WMPs attract savers, but reaching for yield alone does not explain why local banks favor home LGFV bonds over bonds elsewhere. Local knowledge may improve purchase terms or borrower selection, while close ties may also encourage support through lower yields. We examine these motives using issuance pricing, subsequent distress, and purchases under refinancing pressure.

The pricing test asks whether local participation in the primary market benefits WMP investors or the borrower. For each newly issued LGFV bond, we distinguish two groups of WMP buyers: those whose underlying banks are headquartered in the issuer's city, and those whose banks are elsewhere in the same province. These groups differ in the buyers' locations relative to the bond issuer, not in the location of the issuer being studied. Both groups are local banks investing within their home province.

[18]The eleven controls and local-bank indicator enter, while risk and withdrawal levels are absorbed. Product assets are dated at the flow quarter's start and other controls one quarter earlier. The sample is 2022Q3–2025Q3, and errors cluster by underlying bank. Top and bottom groups differ by about one percentage point in prior quarterly return. Internet Appendix D.5 explains inferred assets and peer groups.

Each purchase share measures the fraction of the bond's total issuance absorbed by one buyer group. We proxy purchases with holdings first disclosed in the bond's issue quarter. The same-city purchase share is the amount held by WMPs of same-city banks divided by the bond's total issued amount, and the other-city purchase share uses WMPs of banks elsewhere in that province. We multiply both ratios by 100. A share of 5 therefore represents RMB 50 million of a RMB 1 billion issue, not 5% of a WMP's portfolio or of all WMP holdings.[19]

We then compare each bond's issue pricing with its public secondary-market valuation at listing. The outcome, yield concession, is the valuation spread from China Securities Index Co. (CSI) minus the issue spread, in basis points, with each spread measured relative to Treasury yields. A positive value means the borrower issued at a lower yield, and hence a higher price, than the valuation benchmark, and a negative value means buyers obtained a higher yield. We compare this pricing gap across otherwise similar issues with different buyer shares, rather than prices paid by the two groups for the same issue.[20]

For bond j issued in quarter q, we estimate

$$\begin{aligned} \text{Yield concession}_{jq} = {} & \beta_C \, \text{Same-city purchase share}_{jq} \\ & + \beta_P \, \text{Other-city purchase share}_{jq} \\ & + \gamma' \, \text{Controls}_j + \alpha_{c(j),q} + \varepsilon_{jq}. \end{aligned} \tag{6}$$

Both purchase shares enter the same regression, so each coefficient measures a one-percentage-point increase in that group's share, holding the other group's share constant. Issuer-city–quarter effects $\alpha_{c(j),q}$ compare bonds issued in the same city and quarter, where $c(j)$ is the issuer's city. Controls hold bond terms, issuer administrative level, and overall WMP participation constant.[21]

[19] These issue-quarter holdings proxy for primary-market purchases. Order-level allocations are not observed, and holdings can reflect trading after issuance. Products managed by a bank or its subsidiary are assigned to the underlying bank's headquarters.

[20] CSI provides valuations rather than observed resale prices. The issue-yield proxy uses the fixed-rate bond's coupon, which also enters as a control, so pricing is compared conditional on issue terms.

[21] Controls are log issue amount, maturity, guarantee and call indicators, coupon, county- and prefecture-level issuer indicators, number of participating banks, and total WMP ownership. The sample is 2022Q1–2025Q3.

The pricing patterns differ sharply (Table A11). A one-point larger share purchased by banks elsewhere in the issuer's province is associated with a 0.40-basis-point smaller yield concession, so these issues are less overpriced relative to the valuation benchmark, consistent with informed purchasing. A one-point larger same-city share instead accompanies a 0.61-basis-point larger concession, favoring the borrower. The difference, $\beta_C - \beta_P$, is 1.01 basis points. Shifting one point of participation from other-city provincial buyers to same-city buyers, with their combined share unchanged, is associated with more borrower-favorable pricing. Where proximity should make information especially useful, buyers accept worse relative terms. This pattern is consistent with support that lowers same-city borrowers' financing costs.

To test whether these favorable terms went to borrowers more likely to run into trouble, we replace yield concession in equation (6) with Issuer distress$_{jq}$, equal to 100 if the issuer experiences its first credit event within eight quarters and zero otherwise. We retain both purchase shares, the controls, and city–quarter effects, and add the public valuation spread to compare issuers with similar observed initial risk.[22]

Greater same-city participation is associated with less subsequent issuer distress (Table A12). The pricing test indicates who receives better financing terms, while the distress test asks which borrowers local WMPs select. Lower subsequent distress is consistent with informed selection even when buyers concede some yield to same-city borrowers.

Support need not mean providing financing whenever local borrowers need it. We measure refinancing pressure by the maturity wall, scheduled LGFV principal repayments relative to the issuer city's 2020 budget revenue, and compare home- and outside-province WMP buyers of that city's bonds in the same quarter. When more debt comes due, home buyers reduce

Table errors are heteroskedasticity-robust, and issuer-clustered inference is also reported for the purchase-share contrast.

[22]The sample comprises previously undistressed issuers of 2022Q1–2023Q4 bonds, with complete outcomes through 2025Q4. Credit events include issuer defaults, rating warnings, and guarantor events, not necessarily default on the bond held by the WMP. Coefficients measure percentage-point differences in distress probability per point of the purchase share.

net purchases and favor guaranteed bonds among newly added holdings (Table A8).[23] Local WMPs limit their exposure and seek protection when refinancing needs rise.

Together, the tests suggest that local knowledge and selective borrower support help explain why banks seek yield at home. Support on pricing can coexist with informed selection and caution under repayment pressure. Conceding some yield on selected same-city bonds need not eliminate the product-return advantage from investing more heavily in higher-yielding LGFV bonds.

4 Debt Resolution and the Loss of Bond Yield

The debt-resolution program described in Section 2 changed the yield available from this strategy. By reducing refinancing pressure, it strengthened expected government support for LGFVs.

For WMPs, stronger support had two different implications. Falling spreads could raise the value of bonds already held, but they reduced the yield available when funds were reinvested. The latter threatened the return advantage that local banks used to compete for savers. We first document spread compression and compare bond yields with those on private credit, then examine the loss of the WMP bond-return premium and the response of WMP portfolios.

4.1 LGFV bond-spread compression

LGFV bonds lost much of the extra yield they offered over government bonds. Among newly issued fixed-rate bonds, the average spread over the Treasury yield fell from 200 basis points in 2022Q1–2023Q3 to 97 basis points in 2023Q4–2025Q4, roughly halving. Average LGFV issuance yields fell from 4.18% to 2.70%, while the corresponding Treasury yields fell from

[23] Equations (D.7) and (D.8) in Internet Appendix D.4 also include buyer–quarter effects, and the net-purchase regression further absorbs persistent buyer–city ties. Newly added holdings need not be newly issued bonds.

2.18% to 1.72%. The decline thus went well beyond the general fall in government borrowing rates.[24]

The regional gap also narrowed. Provinces in the highest and lowest quintiles of pre-announcement spreads differed by 564 basis points in 2023Q1 but only 64 by 2025Q4 (Figure A3). Keeping group membership fixed, almost nine-tenths of the gap disappeared, so formerly high-spread regions supplied much less additional yield for reinvestment.

A quarterly event study links this compression to the program (Figure 1). Relative to 2023Q2, and accounting for province and quarter effects, spreads fall more where special refinancing is larger relative to pre-program GDP. The difference emerges with implementation and deepens through 2024. Regressions using cumulative refinancing-bond issuance at each date show the same negative association (Table A4 and Internet Appendix D.2). For WMPs, home LGFV bonds now offered much less additional yield with which to compete for savers.

4.2 Contractual yields on alternative claims

Private credit offered a potential substitute for the lost bond yield. We compare yields on new LGFV bonds with those on new private credit contracts (Figure 2). From 2023Q2 to 2024Q4, average private credit yields fall from 6.6% to 5.9%, while bond yields fall from 4.6% to 2.7%, widening the gap from about 2.0 to 3.2 percentage points. To separate differences between financing instruments from differences in borrowers or maturities, we next compare the same legal borrower in the same financing month and control for maturity.

[24]These are descriptive, equal-issue-weighted averages, without conditioning on WMP ownership. The issue sample differs from the issuer-type comparison in Section 2, so its pre-program average yield differs slightly from the 4.26% reported there. Internet Appendix D.2 gives sample construction and the supporting regressions.

We use an instrument-by-quarter event study to compare the yield gap before and after the announcement. For contract or bond issue j of borrower f in month m, we estimate

$$\begin{aligned}\text{Yield}_{jfm} = \alpha_{fm} + \sum_q \beta_q \, \mathbb{1}\{\text{Private credit}\}_j \mathbb{1}\{q(m) = q\} \\ + \sum_q \gamma_q \, \text{Maturity}_j \mathbb{1}\{q(m) = q\} + e_{jfm}.\end{aligned} \tag{7}$$

The outcome Yield_{jfm} is the annualized contractual borrowing rate, expressed in percent. The indicator $\mathbb{1}\{\text{Private credit}\}_j$ identifies private credit, Maturity_j is maturity in years, and $q(m)$ is the quarter containing month m. Borrower–month effects compare the same legal borrower's two financing channels, excluding affiliates, and a separate maturity slope in each quarter allows the relationship between maturity and yield to change over time. Thus β_q measures the quarter's private-credit-minus-bond yield gap in percentage points.[25]

To present the event study relative to 2023Q2, Figure 3 plots

$$\delta_q = \beta_q - \beta_{q_0}, \qquad q_0 = 2023\text{Q2}, \qquad \delta_{q_0} = 0. \tag{8}$$

The same-borrower comparison confirms that private credit retains more yield. Zero on the plot means an unchanged gap from the 1.90 percentage points in 2023Q2, not equal yields. The gap widens from the second half of 2023, reaching 2.86 points in 2024Q4, 0.96 points above the reference, and remaining 1.06 points above it in 2025Q3. Confidence intervals use the covariance of both gap estimates. Private credit to the same borrower thus remained a higher-yielding alternative, complementing the province-level refinancing evidence above.

Alternative maturity controls, weighting schemes, a fixed borrower cohort, and inference methods retain the later widening (Tables D4–D5). The fixed-borrower rate series explain the pre-announcement trough in 2023Q1: bond yields temporarily rise while private credit

[25]The sums include every sample quarter, so they already span the private-credit and maturity main effects. Quarter indicators are absorbed by borrower–month effects. There are 17,303 observations for 589 borrowers over 2021Q1–2025Q3. Errors cluster by borrower province. Mixed-channel borrower-months identify the direct comparison, while other months inform the maturity controls. Internet Appendix D.2 gives the matching rules.

yields remain stable (Figure D1 and Internet Appendix D.2). The plot therefore describes relative financing terms rather than a parallel-trends estimate of the policy's effect.

A broader comparison, which groups financing by the issuer that reports it and therefore includes affiliates' financing, provides a second check on the financing-channel difference. Within issuer and origination quarter, the private credit-minus-bond gap widens by 1.30 percentage points between 2022 and 2024, controlling for maturity and persistent instrument differences. On common issuer-years, it widens by an additional 1.04 points in the twelve high-debt-risk priority provinces relative to elsewhere (Table 4 and equations (D.3) and (D.5)). Both comparisons show that private credit retained yield within the local borrower sector. Section 5 examines which banks used this alternative.

4.3 Return premiums on bonds and private credit

Contractual yields measure the income available on new financing. We next compare the estimated WMP-return premiums associated with each investment category to establish which investments retained a return advantage. Section 3.3 established the initial premiums using β in equation (4), and we now turn to the Post interactions δ in that same regression. Each interaction measures the change in an asset's premium, and $\beta + \delta$ gives its post-program premium. We retain the same annualized comparison for a 20-point allocation replacing non-home other bonds (Table 3).

Home LGFV bonds lose more of their initial premium than any other asset category. Their annual premium falls from 21.2 to 6.5 basis points for the common 20-point allocation, a loss of 14.7 basis points, or 69%. With product controls alone, the corresponding loss is 16.1 basis points, or 61%. The non-home LGFV premium falls from 7.3 to 1.9 basis points, a loss of 5.4. Home bonds therefore lose about 9.3 basis points more than LGFV bonds elsewhere.

The asset supplying the strongest initial home return advantage also experiences the largest erosion.[26]

Private credit retains more of its contribution to product returns. Its home premium falls from 16.2 to 10.5 annual basis points, a loss of 5.7, and its non-home premium rises from 6.7 to 10.0. Home other bonds have little premium in either period, at 1.2 and 1.4 basis points. The decline in the home LGFV premium is statistically larger than the change in each of these categories.[27] In particular, home LGFV bonds lose about 9.0 annual basis points more than home private credit. This difference matters for substitution, because private credit still offered a positive return premium from local borrowers after much of the bond premium had disappeared.

Part of the lost home LGFV return advantage should reflect the yields on the bonds WMPs hold. To measure this part, we calculate the average yield at which each portfolio's bonds were issued, giving larger holdings more weight, and repeat the return regression with this bond-income proxy added, keeping the same products and months.[28] For a 20-percentage-point greater allocation to home LGFV bonds, the estimated annual premium loss falls from about 15 to 6 basis points (Table E1). Accounting for bond-yield differences thus reduces the estimated loss by roughly three-fifths, consistent with lower bond income contributing to the erosion of the return advantage.

The loss of premium also persists over longer horizons. Reported NAVs may adjust slowly, so gains or losses can appear in a different month from when they occur. We therefore measure each product's average monthly return over a complete six- or twelve-month period and relate it to the portfolio observed before that period begins. This reduces the importance

[26]The raw monthly coefficients for home LGFV exposure are 8.852 before implementation and -6.133 for its Post interaction. Their sum gives the remaining premium, and multiplying each comparison by 0.20×12 gives the annualized 20-point allocation comparison.

[27]Bank-clustered tests using the regression's full covariance matrix give $p = 0.014$ for the difference in changes between home and non-home LGFV bonds, $p = 0.015$ between home LGFV bonds and home private credit, $p = 0.002$ against home other bonds, and $p < 0.001$ against non-home private credit. The 20-point comparisons multiply the raw monthly coefficients by 0.20×12 and do not standardize the regressors.

[28]We add the average bond issue yield and its Post interaction, allowing the relationship between bond yields and WMP returns to differ before and after the program. All other regressors and controls remain unchanged.

of which month records a valuation change. For the same 20-point allocation comparison, the annualized home LGFV premium loss remains about 16 basis points over six-month windows and 13 over twelve-month windows. Home private credit, by contrast, retains positive post-program premiums of about 13 and 12 basis points, respectively (Table E2).[29] The contrast between bonds and private credit therefore remains when performance is measured over half a year or a full year, rather than one month.

Together, the financing and product-return comparisons establish the change in investment opportunities: home LGFV bonds lost much of their yield contribution, while private credit retained a return premium. The next subsection turns to how banks adjusted their portfolios.

4.4 Retreat from home LGFV bonds

As home LGFV bonds lost their return advantage, local banks reduced the positions that had supported their strategy. We first ask which banks retreated most, testing whether WMPs of institutions initially more oriented toward home investments reduced home LGFV bonds more as refinancing proceeded. Comparing local-bank products in the same home province and quarter, we estimate

$$\begin{aligned}\text{Home LGFV bond share}_{iq} = \beta\, &\text{Initial home overweight}_{a} \times \text{Refinancing}^{debt}_{p_b,q} \\ &+ \gamma' \,\text{Controls}_{iq} + \alpha_a + \alpha_{p_b,q} + \varepsilon_{iq}.\end{aligned} \tag{9}$$

The outcome is the product's home LGFV bond share in percentage points. Initial home overweight is the issuing institution's product-size-weighted 2022Q1–2023Q3 average home investment above provincial market weights, summed across bonds and private credit as defined in Section 3.2. Refinancing is cumulative special-refinancing bond issuance divided by 2020 LGFV debt in the underlying bank's home province. Institution and home-province–quarter effects hold persistent portfolio differences and common regional conditions fixed. A

[29] These are the winsorized-return specifications in columns 2 and 4. All magnitudes are annualized for comparison with the monthly baseline and are not cumulative six- or twelve-month returns. Internet Appendix E gives the window dates, starting exposures, controls, and bank-clustered inference.

negative β means that initially more home-oriented institutions reduce home bonds more as refinancing rises.[30]

The reduction is greater at institutions initially more concentrated at home (Table 5). For two institutions differing by ten percentage points in initial home overweight, a ten-point rise in refinancing relative to initial LGFV debt is associated with 0.46 percentage points more home-bond retreat at the more home-oriented institution (wild-bootstrap $p = 0.010$). Using strictly pre-announcement reliance or allowing it separate quarterly paths gives similar estimates.

The second test asks whether home banks pulled back more than other buyers of bonds from the same city. This distinction matters because lower holdings alone could reflect fewer local bonds being available, rather than a change in banks' preference for them. We therefore compare changes in the allocations of home and other WMP buyers within the same issuer city and quarter:

$$\begin{aligned} \text{LGFV bond share}_{acq} = \beta\, \mathbb{1}\{\text{Home buyer}\}_{ac} \times \mathbb{1}\{\text{Post}\}_q \\ + \mu_{ac} + \mu_{aq} + \mu_{cq} + \varepsilon_{acq}. \end{aligned} \tag{10}$$

Each observation is a buying institution a, an LGFV issuer city c, and a quarter q. The outcome is that city's LGFV bonds as a percentage of the institution's total WMP bond holdings. Home equals one for a local bank investing in a city of its headquarters province, and the comparison group comprises the other buyers, including national banks. Post begins in 2023Q4. City–quarter effects μ_{cq} absorb changes in local bond supply and other city conditions shared by buyers. Buyer–quarter effects μ_{aq} absorb changes across a buyer's portfolio, and buyer–city effects μ_{ac} absorb persistent investment ties. The coefficient β

[30] Both interaction variables are fractions. The eleven time-varying controls enter, and errors and wild-bootstrap draws cluster by home province. The refinancing denominator is LGFV debt, not GDP as in the spread tests.

therefore measures whether home buyers cut their allocation to that city's bonds more than other buyers after implementation, beyond these common changes.[31]

Home buyers cut their allocation by an additional 0.45 percentage points per issuer city relative to other buyers (Table 6). This is about 12% of their pre-program mean allocation of 3.91%. The decline is greatest for bonds from their own city. Net buying and new purchases also fall, with larger purchase reductions in cities whose bonds previously offered higher spreads. This is a retreat specific to home buyers, beyond a contraction in the local bond market shared by all buyers.

The event study in Figure 4 traces the timing of this relative retreat. It repeats the home-versus-other-buyer comparison for an entire destination province rather than a single city, replacing Home–Post with quarterly interactions and retaining the corresponding fixed effects. Relative to the 2023Q2 allocation gap, home buyers' allocation falls by 2.3 percentage points in 2024Q1 and 6.1 by 2025Q3, while pre-announcement confidence intervals include zero. These province-wide changes are not directly comparable in size to the per-city estimate above. Adjustment can occur through sales or by letting bonds mature without replacing them. Initially home-oriented institutions retreated more, and home buyers reduced their allocations more than other buyers of the same local market. The next question is which banks could replace the lost yield.

5 Bank Size, Private Credit, and Competition

The loss of home LGFV bond yield left local banks with a commercial problem: how to maintain the returns they offered savers. Private credit retained higher contractual yields and a positive product-return premium, but banks differed sharply in their use of it. Larger local banks expanded this substitute, while the smallest rarely held it, even in new portfolios. We examine how this unequal adjustment relates to returns and fundraising through newly

[31] Home and Post levels and bank/city controls are absorbed. Errors cluster by bank city. Internet Appendix D.4 defines the additional outcomes and event-study specification.

launched WMPs, distinguishing banks' initial exposure to the lost bond yield from their subsequent expansion into private credit.

5.1 Which local banks shifted into private credit

Private credit had initially been concentrated at national banks. Before implementation, they held 82.7% of its identified value in our sample, mostly outside their headquarters provinces (Table 7). Local banks' share subsequently rose from 17.3% to 31.3%. Within local banks' portfolios, home private credit increased from 6.1% to 13.9% of included debt holdings, more than the increase outside their provinces. An instrument used predominantly by national banks became a more important source of yield for local banks investing at home.[32]

This shift was concentrated among larger local banks. Among banks observed in both periods, the largest third increased home private credit from 7.45% to 18.26% of their included debt holdings. This increase more than offset their decline in home LGFV bonds, and together the two investments rose from 28.1% to 33.2%. At the smallest third, home private credit remained negligible, falling from 0.72% to 0.31%, while the combined share fell from 25.8% to 21.1%. The middle group substituted modestly. Larger banks therefore expanded an instrument already present in their portfolios, while the smallest reduced home investments without building a comparable substitute. The size groups use fixed FY2021 assets, so these differences do not arise from reclassifying banks after the program.

The change was largely in the form of financing rather than a departure from the LGFV sector. Matching private-credit borrowers to LGFV bond issuers, and screening borrower names for terms typical of LGFVs, identifies 85% of the largest local banks' post-program home private credit value as LGFV-linked (Internet Appendix D.1). As bond yields fell, larger banks shifted toward less transparent claims within the local LGFV sector.

[32]These are descriptive, holding-value-weighted shares over 2022Q1–2023Q3 and 2023Q4–2025Q3. The national–local percentages describe each group's share of all private credit in the sample, and the portfolio percentages divide home private credit by each group's included debt holdings.

5.2 Bank size and the shift into private credit

The portfolio averages suggest that larger local banks replaced lost bond yield with private credit, while smaller banks made little use of this substitute. We test whether this difference remains after accounting for product characteristics, bank conditions, and local economic conditions. For local-bank product i, issued by bank b, in quarter q, we estimate

$$\begin{aligned}\text{Private credit share}_{iq} = {} & \beta_M \, \mathbb{1}\{\text{Middle tercile}\}_b \times \mathbb{1}\{\text{Post}\}_q \\ & + \beta_L \, \mathbb{1}\{\text{Largest tercile}\}_b \times \mathbb{1}\{\text{Post}\}_q \\ & + \gamma' \, \text{Controls}_{iq} + \alpha_b + \alpha_q + u_{iq}.\end{aligned} \tag{11}$$

The outcome is home or total private credit as a percentage of the product's included debt holdings. Banks remain in their FY2021 asset terciles, and Post begins in 2023Q4. The smallest tercile is the comparison group. Bank effects remove persistent allocation differences, and quarter effects remove common changes. Thus β_L measures how much more the largest group's private-credit share changes after implementation than the smallest group's share. We weight each product-quarter by the value of its included debt holdings, giving larger portfolios more weight.[33]

The largest group's home private credit share rises by 8.21 percentage points more than the smallest group's share, and the difference for total private credit is 10.46 points (Table 8). Both are significant at the 1% level. Most of the additional expansion at large local banks occurs in their home provinces. Figure 5 illustrates this contrast: national banks already used private credit extensively outside their headquarters provinces, whereas larger local banks expanded it primarily at home.

The size difference could instead reflect banks' initial orientation toward home investments. To check, we allow initial home overweight and log FY2021 bank assets to predict post-program adjustment separately, retaining institution effects, the eleven controls, and

[33]The sample covers 2022Q1–2025Q3. The eleven controls are those in equation (4). Errors cluster by underlying bank. Fixed group indicators and Post are absorbed by the fixed effects.

home-province–quarter effects. Among banks facing the same provincial conditions, a bank twice as large increases its home private credit share by about 4.1 percentage points more, conditional on initial home orientation (Table 9, Panel B). Internet Appendix D.9 gives this specification and its refinancing-intensity version, together with the continuous-size and top-tenth comparisons.[34]

Private credit thus allowed larger local banks to retain more investment in home borrowers as they reduced home LGFV bonds, and the combined allocation also rises more with bank size (Table A13). The next subsection examines whether smaller banks' limited substitution persists in newly launched products, where legacy bond positions need not constrain portfolio choice.

5.3 Portfolio choice in new products

Existing portfolios may adjust slowly because of their maturity structure or withdrawal terms. New products let banks choose a fresh portfolio. We therefore compare the first eligible holdings of WMPs launched in 2023Q4–2025Q3 across the same fixed size groups, asking both whether private credit appears at all and how much of the new portfolio it occupies. This separates limited use of the instrument from an inability to launch products.[35]

The smallest banks did launch new products, but almost none used the substitute. Only two of their 253 new products held home private credit, compared with about 21% at the largest banks (1,118 of 5,248 products, Table 10). Home private credit represented just 0.78% of the smallest banks' new-product debt holdings, versus 27.5% at the largest banks. Home LGFV bonds still accounted for 29.4% at the smallest banks. Their new portfolios continued

[34]The continuous-size comparison also shows greater expansion at larger banks (Table D2). Comparing the largest tenth with the remaining banks gives 9.49 percentage points more home private credit with equal bank-quarter weights, while retaining investment-value weights within each bank-quarter (Table D3). These are complementary comparisons, not alternative estimates of the tercile difference.

[35]Launch is identified by the income-start date rather than first disclosure. Seven products disclosed before their recorded start date are excluded. Banks retain their FY2021 size groups. Portfolio shares are holding-value weighted, and product counts are unweighted.

to use the accessible bond investment rather than taking up private credit. Requiring disclosure in the launch quarter or the next quarter gives the same pattern.

Smaller banks' limited substitution therefore cannot be attributed solely to existing products' legacy bond positions. We next examine what these investment differences meant for the returns offered to savers and the money raised through newly launched WMPs.

5.4 Return losses and private-credit substitution

The earlier return regressions showed that the premium associated with home LGFV bonds fell while private credit retained a premium (Section 4.3). We now examine which banks lost more return by including initial home LGFV reliance, subsequent private-credit expansion, and initial bank size together in one regression. This joint comparison separates exposure to lost bond yield from use of the substitute, conditional on size and initial private-credit holdings.

For underlying bank b in month m, the outcome is its average WMP log return in basis points. Equations and tables retain monthly units. We multiply by 12 when discussing annualized magnitudes. The full joint specification is

$$\begin{aligned}\text{Monthly return}_{bm} = {} & \beta_L \,\text{Initial home LGFV share}_b \times \mathbb{1}\{\text{Post}\}_m \\ & + \beta_P \,\Delta\text{Home PC share}_b \times \mathbb{1}\{\text{Post}\}_m \\ & + \beta_S \,\text{Log bank size}_b \times \mathbb{1}\{\text{Post}\}_m \\ & + \beta_H \,\text{Initial home PC share}_b \times \mathbb{1}\{\text{Post}\}_m \\ & + \gamma' \,\text{Controls}_{b,h(m)} + \alpha_b + \alpha_m + u_{bm}.\end{aligned} \tag{12}$$

Initial home LGFV and private-credit shares divide the bank's respective home holdings by included debt holdings, aggregating holding values over 2022Q1–2023Q2. They are raw fractions, not deviations from market weights. The expansion measure ΔHome PC share$_b$ is the bank's average quarterly home private-credit share in 2023Q4–2025Q3 minus its average

in 2022Q1–2023Q2. Size is log FY2021 interest-bearing assets. All four bank characteristics enter interacted with Post. Bank effects absorb their levels, month effects absorb Post, and the eight prior-quarter bank and home-city controls enter through $\text{Controls}_{b,h(m)}$.[36]

The coefficient β_L asks whether greater initial bond reliance predicts a larger return loss, given subsequent substitution and size. The coefficient β_P asks whether banks that expanded private credit preserved more return, given their initial portfolios and size. Including initial private credit distinguishes expansion from simply having held more of the instrument before the program. The size coefficient β_S measures the remaining size-related difference after these investments are held fixed.

Both investment measures matter in the joint regression (Table 12, Panel A, column 2). Ten percentage points more initial home LGFV exposure predicts about 16 basis points more annualized return decline ($p < 0.001$), while a ten-point larger expansion in home private credit is associated with about 11 basis points less decline ($p = 0.039$). Banks initially more reliant on the bonds lost more return, while banks making greater use of the substitute preserved more. Column 1 retains all four interactions but omits the eight lagged controls.

With initial portfolios and private-credit expansion included, the additional size–Post coefficient is not statistically distinguishable from zero.[37] The allocation evidence explains why. Smaller banks combined substantial home-bond reliance with little substitution, whereas larger banks expanded private credit. The joint estimates are therefore consistent with an investment channel rather than a separate return advantage from size itself. Section 5.6 measures how smaller banks fared overall without holding these two investment measures fixed.

A separate comparison based only on initial bond exposure and size also predicts larger losses at more exposed banks (Table E5). It omits both private-credit interactions and uses

[36]We average monthly log returns across NAV series within product-month, then across products within bank-month. The sample is July 2022–September 2025, excluding July–September 2023. Post begins in October 2023. Each bank-month receives equal weight, and errors cluster by bank. Internet Appendix E.4 details the exposure and expansion measures.

[37]The size–Post coefficient is 0.298 monthly basis points per log point of FY2021 assets, with a bank-clustered standard error of 0.759.

bank effects and subsidiary-status-by-month effects. With the eight lagged controls, ten points more initial home LGFV exposure predicts about 13 basis points more annualized return decline (wild $p = 0.003$). The relationship survives province-by-month effects and separate quarterly size slopes (Internet Appendix E.3). Initial reliance thus predicts losses even without conditioning on banks' subsequent substitution.

5.5 Fundraising through newly launched WMPs

We next test whether banks with greater bond reliance also raised less money through newly launched WMPs, and whether those that expanded private credit raised more. Small banks continued launching WMPs despite their limited substitution (Section 5.3), but product launches alone do not tell us how much money they attracted. We use total balances across each bank's newly launched WMPs as a fundraising proxy and relate them to the same initial bond reliance and private-credit expansion examined in the return tests.

For local bank b and launch quarter q, we sum the balances of observed products launched in q, measured at the end of $q+1$. Products are then roughly three to six months old. We call this sum new-product balances and use its log as the fundraising proxy. It reflects both the number of products launched and their balances. We estimate the same joint comparison for this outcome:

$$\begin{aligned}\text{Log new-product balances}_{bq} = {} & \beta_L \,\text{Initial home LGFV share}_b \times \mathbb{1}\{\text{Post}\}_q \\ & + \beta_P \,\Delta\text{Home PC share}_b \times \mathbb{1}\{\text{Post}\}_q \\ & + \beta_S \,\text{Log bank size}_b \times \mathbb{1}\{\text{Post}\}_q \\ & + \beta_H \,\text{Initial home PC share}_b \times \mathbb{1}\{\text{Post}\}_q \\ & + \gamma' \,\text{Controls}_{b,q-1} + \alpha_b + \alpha_q + u_{bq}.\end{aligned} \tag{13}$$

Initial shares, private-credit expansion, and bank size have the same definitions as in equation (12), and the same eight bank and home-city controls lag one quarter. Bank effects α_b

absorb the fixed bank-characteristic levels, and launch-quarter effects α_q absorb common changes, including Post. Post starts with launches in 2023Q4. Each bank–launch quarter receives equal weight, and errors cluster by bank. Column 4 of Table 12 reports this full specification. Column 3 omits the private-credit-expansion interaction. The sample covers launches in 2022Q2–2025Q2, excluding 2023Q3, and unobserved cohorts are not assigned zero balances. Internet Appendix E.5 gives the construction and sample requirements.

Greater initial bond reliance predicts both larger return losses and weaker fundraising through newly launched WMPs. In column 3 of Table 12, Panel B, a ten-percentage-point greater initial home LGFV share predicts 14.4% lower new-product balances after the program, relative to the pre-program difference and after accounting for size and initial private-credit holdings ($p = 0.004$). A bank twice as large has 16.8% greater relative growth in these totals ($p = 0.009$). The comparison uses 647 bank–launch quarters.

The full joint regression in column 4 asks whether banks that expanded private credit also raised more money through newly launched WMPs. A ten-point larger increase is associated with 14.6% greater relative growth in new-product balances ($p = 0.034$), conditional on initial bond reliance, private-credit holdings, and size. Ten points more initial home LGFV reliance still predicts 15.3% lower totals ($p = 0.002$). The size coefficient falls from 0.224 to 0.138 and is no longer statistically significant.[38] As in the return regression, initial reliance and subsequent substitution predict performance after accounting for bank size, while size contributes less once those investments are held fixed. The fundraising difference is thus closely related to what banks held before the program and how much private credit they added afterward.

[38]Column 4 uses the 641 bank–launch quarters with sufficient pre- and post-program holdings to measure expansion. Re-estimating column 3 on these same observations gives nearly unchanged reliance and size comparisons: −14.1% for ten points more reliance and +16.2% for a doubling of size. Tables report unstandardized coefficients, and percentage effects in the text use $100[\exp(\beta\Delta x) - 1]$.

5.6 Bank size and relative performance

The joint regressions ask which investment differences accompany losses in returns and fundraising, holding size constant. We now ask how smaller banks fared relative to larger banks overall. This comparison leaves initial home LGFV bond exposure and subsequent private-credit expansion out of the regression: holding them fixed would remove the investment differences through which our mechanism links size to performance. We examine product returns and total outstanding WMP balances, including older products. The return specification still controls for the broader initial home overweight.

For product returns, each observation is a NAV-series–month, as in equation (4). We follow the allocation design in Internet Appendix D.9, equation (D.14), and relate performance to initial size and refinancing intensity:

$$\begin{aligned}\text{Monthly return}_{im} = {} & \beta_S \,\text{Log bank size}_b \times \text{Refinancing}^{debt}_{p_b,m} \\ & + \beta_B \,\text{Initial home overweight}_a \times \text{Refinancing}^{debt}_{p_b,m} \\ & + \gamma' \,\text{Controls}_{i,h(m)} + \alpha_a + \alpha_{p_b,m} + \varepsilon_{im}.\end{aligned} \tag{14}$$

The size measure Log bank size$_b$, prior reliance Initial home overweight$_a$, and home-province intensity retain their earlier definitions. The outcome Monthly return$_{im}$ is in basis points, and the eleven controls are measured at the preceding quarter end $h(m)$. The quarterly intensity series is assigned to the months of its quarter. Issuing-institution effects remove persistent performance differences, and home-province-by-month effects compare banks facing the same regional conditions. A second version replaces intensity with $\mathbb{1}\{\text{Post}\}_m$ in both interactions. In each version, β_S measures the widening of the size-related return gap, conditional on prior reliance.[39]

[39]These regressions are unweighted, and errors cluster at the bank-city-by-month level. Issuing-institution effects absorb fixed size and reliance, while province-by-month effects absorb intensity or Post levels. A positive size interaction denotes a widening return gap in favor of larger banks.

The relative return gap widens alongside unequal substitution. After implementation, the annualized product-return difference between a bank and one twice as large widens by about 10.3 basis points (Table 9, Panel B). The intensity version gives the same direction: when refinancing rises by ten percentage points of initial provincial LGFV debt, the annualized return difference associated with a doubling of bank size widens by about 11.6 basis points (Panel A).[40] For perspective, applying the lost home LGFV premium to local banks' average initial holdings implies about 19 annualized basis points of lost return. The return gap is therefore large relative to the bond-income advantage that disappeared.

To date when smaller banks began losing ground in returns, we extend equation (14) to a size-by-quarter event study, replacing both refinancing interactions with log bank size interacted with quarter indicators and omitting 2023Q3. The monthly return outcome, eleven controls, and fixed effects are unchanged, and prior-reliance interactions are not included. Figure 6 plots the change in the size–return relationship in each quarter relative to 2023Q3, in monthly basis points per log point of assets.[41]

The event study shows the return gap developing gradually rather than jumping at the announcement. There is a short-lived positive estimate in 2022Q2, followed by pre-program fluctuations. The sustained widening begins in 2024Q3 and remains positive through 2025Q3. For a bank twice as large, the plotted changes imply about 33 annualized basis points more relative return in 2024Q3 and 45 in 2025Q3.[42] Initial exposure identifies where bond-income losses mattered most, and the event study dates the subsequent widening of the size-related return gap.

[40]The raw size–Post coefficient is 1.2345 monthly basis points per log point of assets, giving $1.2345 \times \ln 2 \times 12 = 10.3$ annualized basis points. The size–intensity coefficient is 13.93, giving $13.93 \times 0.10 \times \ln 2 \times 12 = 11.6$ annualized basis points.

[41]The sample covers 2022Q2–2025Q3. Observations are unweighted. Errors cluster by underlying bank rather than bank city–month as in the average comparisons. Fixed size is absorbed by institution effects, and quarter indicators by province–month effects.

[42]The plotted coefficients remain in monthly units: 3.98 and 5.46 basis points per log point of assets. Multiplying by $\ln 2 \times 12$ gives the annualized doubling comparisons. These quarter-specific differences are not an arithmetic decomposition of the pooled Post coefficient. Re-estimating the pooled regression with the event study's controls gives 1.284 monthly bp per log point. Projecting the quarterly coefficients onto the pooled comparison, with the same observations, controls, and fixed effects, also gives 1.284. Adding initial home overweight × Post gives the 1.234 coefficient in Table 9.

To test whether the size-related return gap is accompanied by a difference in overall WMP-business growth, we estimate, for local bank b at half-year end s,

$$\begin{aligned}\text{Log WMP balances}_{bs} = \beta_S \,\text{Log bank size}_b \times \mathbb{1}\{\text{Post}\}_s \\ + \alpha_b + \alpha_s + \varepsilon_{bs}.\end{aligned} \tag{15}$$

The outcome is log total WMP balances. Size is log FY2021 bank assets in RMB trillion, and Post begins with the December 2023 report. Bank effects α_b remove persistent differences in WMP balances. Half-year effects α_s remove common growth. The coefficient β_S asks whether the proportional balance change after implementation is greater at initially larger banks. Column 2 of Table 11 replaces common half-year effects with province-by-half-year effects, and column 3 replaces continuous size with fixed size-tercile indicators interacted with Post.[43]

Smaller banks' weaker relative performance is accompanied by weaker WMP-business growth (Table 11). A bank twice as large experiences about 11% greater proportional WMP-balance growth after implementation, relative to the initial difference. The raw size–Post coefficient is 0.152 log balance points per log point of assets. Comparing banks within the same province and half-year gives 0.144, implying about 10.5% greater growth for a doubling of size. Across the fixed size groups, the largest third grows about 40% more than the smallest.[44]

A fixed-bank comparison makes the contraction at the smallest institutions concrete. Among the smallest banks reporting in both June 2023 and December 2024, aggregate WMP balances fall by 22.0%, and every one of these banks shows a decline.

To trace when smaller banks lost ground in WMP business, we replace the size–Post interaction in equation (15) with size interacted with each half-year reporting date, omitting

[43]The panel covers 2022H1–2025H2. Fixed size is absorbed by bank effects and Post by time effects. There are no additional controls because the bank-level panel is sparse, and errors cluster by bank. For an asset ratio a, the implied relative growth difference is $100[\exp(\beta_S \log a) - 1]\%$. Missing reports are not zeros. Balances measure WMP business scale, combining investment returns, product entry and maturity, and investor transactions. Internet Appendix E.1 gives coverage and measurement details.

[44]For a 0.981-log-point standard deviation of size, the baseline and province-time estimates imply about 16% and 15% greater relative growth. These are calculated from the raw coefficients, and size is not standardized.

June 2023. This event study retains the baseline's bank and half-year effects, bank-clustered errors, and absence of additional controls. Figure 7 plots the change in the size–balance relationship relative to June 2023, per log point of FY2021 bank assets. The sample covers 2022H1–2025H2, and the quarterly axis shows actual reports at Q2 and Q4, without interpolating Q1 or Q3 balances.

The two 2022 estimates are close to zero, and little of the later separation is present by December 2023. The size-related growth gap then increases during 2024 and is larger in 2025. For a bank twice as large, the path implies roughly 11% greater relative growth by December 2024 and 26% by December 2025, compared with June 2023.[45] The late-period difference exceeds the average 11% Post comparison because that average also includes the earlier reports when the gap was much smaller. The event study shows a growing business difference that broadly tracks the later separation in product returns.

We check whether this business divergence depends on who reports or on organizational form. Table E3 retains only banks observed at every date, separately excludes the final period, and allows banks with different organizational forms separate time paths. The positive size-related growth difference remains, as it does separately below and at or above RMB50 billion of June 2023 WMP balances. The size gradient therefore does not simply reflect this cutoff or the difference between banks with and without subsidiaries. Internet Appendix E.1 gives the sample definitions and results.

Together, the comparisons show both smaller banks' loss of ground and the investment differences associated with it. Initial home LGFV reliance predicts larger return losses and weaker fundraising through newly launched WMPs. Private-credit expansion predicts better return preservation and stronger fundraising. Once these investments are held fixed, the joint regressions detect no additional size effect. The separate size comparisons retain banks' differing exposure and substitution and show that smaller banks lost ground in product returns

[45] The raw log-balance coefficients are 0.146 and 0.334 per log point of assets. The doubling comparisons are $100[\exp(0.146 \ln 2) - 1] \approx 11\%$ and $100[\exp(0.334 \ln 2) - 1] \approx 26\%$. The joint test for the two 2022 coefficients gives $p = 0.094$.

and total WMP balances. This is the role of size in our mechanism: smaller banks relied on bond yield to compete but made little use of the substitute when that yield disappeared.

6 A Model of Unequal Adjustment

The model explains why the banks that most need high yields are not the banks best able to replace them. A weaker reputation makes yield more important for winning savers, but a smaller investor base limits the fee income available to cover the fixed cost of establishing private credit. Existing users can expand private credit when bond yields fall. Other banks must first find entry worthwhile. We take the documented home orientation of investment as given and derive how saver choice and portfolio choice interact.[46] Internet Appendix B derives the conditions and computes an illustrative full equilibrium, and Internet Appendix C gives proofs.

6.1 Savers and banks

A bank in the model represents its WMP business, including any wealth-management subsidiary, and the investments below belong to its products, not its own balance sheet. A unit mass of savers each invests one unit with a bank or an outside saving option. Savers differ in risk aversion γ_h, drawn from a nondegenerate distribution G on a bounded positive interval. Saver h obtains utility

$$U_{hb} = \gamma_h a_b + \beta\left(R_b - \frac{\gamma_h}{2} V_b\right) + \varepsilon_{hb} \tag{16}$$

from bank b, and utility ε_{h0} from the outside option. Each saver chooses the alternative with the highest utility. Here R_b and V_b are expected excess return and return variance, so $R_b - \frac{\gamma_h}{2} V_b$ is the risk-adjusted return to saver h, and $\beta > 0$ measures how strongly choices

[46] The two layers of demand follow Darmouni et al. (2024): savers choose institutions, which choose assets. Heterogeneous saver demand draws on Xiao (2020) and random-coefficient demand models (Berry et al. 1995), and fee-based portfolio incentives follow La Spada (2018).

respond to it. The positive return–flow relationship in Section 3 motivates this demand channel. The term a_b captures reputation and distribution. We assume cautious savers place greater weight on reputation, setting that weight equal to γ_h. The taste term ε_{hb} captures preferences such as a nearby branch or an existing account.[47] Among savers with risk aversion γ, the share choosing bank b is

$$s_b(\gamma) = \frac{\exp\left(\gamma a_b + \beta(R_b - \gamma V_b/2)\right)}{1 + \sum_j \exp\left(\gamma a_j + \beta(R_j - \gamma V_j/2)\right)}, \tag{17}$$

and the bank's market share is $s_b = \int s_b(\gamma)\, dG(\gamma)$. There are three banks, a national bank N, a large local bank L, and a small local bank S, with reputations $a_N > a_L > a_S$. The sum in the denominator runs over them, and the term 1 represents the outside option. Holding portfolios fixed, a stronger reputation attracts more savers. Market share measures scale in the model, and the empirical comparisons use the bank's log FY2021 assets, Log bank size$_b$, as predetermined scale.

Each bank invests its products' funds in one portfolio. It places a share x_b in LGFV bonds, a share n_b in private credit linked to the same borrower sector, and the rest in accessible low-yielding assets with riskless return r_f, with $x_b, n_b \geq 0$ and $x_b + n_b \leq 1$. Bonds and private credit earn positive expected excess returns μ_B and μ_{PC} over r_f, net of expected credit losses. Their variances are σ_B^2 and σ_{PC}^2. We assume a positive covariance $\sigma_{B,PC} > 0$ to capture their common exposure to the LGFV sector. The portfolio's expected excess return and variance are

$$R_b = \mu_B x_b + \mu_{PC} n_b, \qquad V_b = \sigma_B^2 x_b^2 + 2\sigma_{B,PC} x_b n_b + \sigma_{PC}^2 n_b^2. \tag{18}$$

We assume $\sigma_{PC}^2 > \sigma_B^2 > \sigma_{B,PC}$: private credit has greater return variance than bonds, and the two are imperfectly correlated. All banks face the same asset returns and risks. Their

[47] The taste shocks, including the outside-option shock, are independent of risk aversion and independently and identically distributed type I extreme value across alternatives and savers. This logit assumption yields equation (17). See Berry (1994) and, for bank deposits, Xiao (2020).

portfolio differences arise from the savers they attract and whether entering private credit is worthwhile.

A bank earns a fee f per yuan of savings. Initiating private credit requires a one-time fixed cost $F > 0$ for sourcing, evaluation, and contracting. The bank pays it when it first arranges private credit, rather than for each product or contract, and the cost is sunk afterward. Taking rivals' portfolios as given, the bank chooses its portfolio to maximize

$$f\, s_b - F\, \mathbb{1}\{n_b > 0\}\, e_b, \tag{19}$$

where $e_b = 1$ if the bank has not arranged private credit before and $e_b = 0$ otherwise. Conditional on whether it enters, a bank maximizes the savings it attracts. Entry must also generate enough additional fee income to pay the fixed cost.[48]

6.2 Portfolio choice

A bank's portfolio choice depends on the savers most likely to change their choice when its offer improves. Holding rivals' offers fixed, a unit increase in the utility offered to type γ, excluding the taste shock, raises the bank's share of that type at rate $s_b(\gamma)\big(1 - s_b(\gamma)\big)$. This response is small when the bank attracts almost none or almost all of that type. Weighting each type by its response gives the average risk aversion of the bank's marginal savers:

$$\bar{\gamma}_b = \frac{\int \gamma\, s_b(\gamma)\big(1 - s_b(\gamma)\big)\, dG(\gamma)}{\int s_b(\gamma)\big(1 - s_b(\gamma)\big)\, dG(\gamma)}. \tag{20}$$

We write $\mathrm{Var}_b(\gamma)$ for the dispersion of risk aversion among these marginal savers, using the same weights. This differs from V_b, the variance of portfolio returns. At an optimum with positive holdings and $x_b + n_b < 1$, the marginal effect of each asset held on market share

[48] We compare two one-period portfolio-and-entry games, before and after an unanticipated reform. Banks maximize fee income in each state, and prior entry carries over through $e_b = 0$. Thus, the model does not assign an additional continuation value to entering before the reform. A Nash equilibrium consists of portfolios and entry decisions that are best responses to the other banks' choices in that state.

must be zero. The resulting first-order conditions are

$$\mu_B = \bar{\gamma}_b\Big(\sigma_B^2 x_b + \sigma_{B,PC} n_b\Big), \qquad \mu_{PC} = \bar{\gamma}_b\Big(\sigma_{B,PC} x_b + \sigma_{PC}^2 n_b\Big). \tag{21}$$

Each condition equates an asset's expected excess return to its marginal risk, valued by the bank's marginal savers. The first condition applies when the bank holds bonds, and the second when it also holds private credit. To make the portfolio choice explicit, we hold marginal-saver composition, and hence $\bar{\gamma}_b$, fixed. This benchmark maximizes their risk-adjusted return, while the full demand problem also accounts for changes in who is marginal. Internet Appendix B.6 solves that problem numerically. For the interior portfolios considered here, the bond-only regime sets $n_b = 0$ and gives

$$x_b^B = \frac{\mu_B}{\bar{\gamma}_b\, \sigma_B^2}. \tag{22}$$

If the bank arranges private credit, the bond condition gives $x_b = x_b^B - (\sigma_{B,PC}/\sigma_B^2) n_b$: private credit adds exposure to the same borrower sector, so the bank reduces its bond share by $\sigma_{B,PC}/\sigma_B^2$ for each unit of private credit. Substituting this bond share into the private credit condition gives

$$\mu_{PC} - \frac{\sigma_{B,PC}}{\sigma_B^2}\,\mu_B = \bar{\gamma}_b\left(\sigma_{PC}^2 - \frac{\sigma_{B,PC}^2}{\sigma_B^2}\right) n_b. \tag{23}$$

The left side is the return that private credit earns beyond the bonds it displaces, and the right side is the risk it adds beyond those bonds. Solving,

$$n_b^{PC} = \frac{\mu_{PC} - (\sigma_{B,PC}/\sigma_B^2)\,\mu_B}{\bar{\gamma}_b\Big(\sigma_{PC}^2 - \sigma_{B,PC}^2/\sigma_B^2\Big)}, \qquad x_b^{PC} = x_b^B - \frac{\sigma_{B,PC}}{\sigma_B^2}\, n_b^{PC}, \tag{24}$$

and private credit raises the risk-adjusted return to the bank's marginal savers by

$$g_b = \frac{\Big(\mu_{PC} - (\sigma_{B,PC}/\sigma_B^2)\,\mu_B\Big)^2}{2\bar{\gamma}_b\Big(\sigma_{PC}^2 - \sigma_{B,PC}^2/\sigma_B^2\Big)}. \tag{25}$$

We impose $\mu_{PC} > (\sigma_{B,PC}/\sigma_B^2)\mu_B$, so private credit earns more than the bonds it displaces and n_b^{PC} and g_b are positive. We also restrict attention to parameters for which both portfolios are interior.[49] With marginal savers held fixed, the bank chooses (x_b^{PC}, n_b^{PC}) if it arranges private credit and $(x_b^B, 0)$ otherwise.

6.3 Who serves cautious savers

Reputation determines not only how many savers a bank attracts but also which ones. For any two banks, equation (17) gives

$$\log \frac{s_b(\gamma)}{s_{b'}(\gamma)} = \beta\Big(R_b - R_{b'}\Big) + \gamma\Big[\Big(a_b - a_{b'}\Big) - \frac{\beta}{2}\Big(V_b - V_{b'}\Big)\Big]. \tag{26}$$

The bracket combines the reputation gap with the difference in portfolio risk. When it is positive, which we call the sorting condition, more risk-averse savers are relatively more likely to choose the more reputable bank. Portfolio choice depends on marginal savers. To obtain transparent comparative statics, we use the small-share approximation: when $s_b(\gamma)$ is small, the marginal-saver weight $s_b(\gamma)(1 - s_b(\gamma))$ is approximately $s_b(\gamma)$. The two saver distributions coincide in this limit. Holding portfolios fixed, reputation then raises marginal risk aversion and market share at the rates

$$\frac{\partial \bar{\gamma}_b}{\partial a_b} = \mathrm{Var}_b(\gamma) > 0, \qquad \frac{\partial \log s_b}{\partial a_b} = \bar{\gamma}_b \tag{27}$$

(Proposition B.1). Under the scale condition below, allowing portfolios to adjust preserves these signs. Higher-reputation banks attract more cautious savers, while lower-reputation banks offer more bond exposure to savers willing to bear risk. The higher bond share in equation (22) therefore helps compensate for a weaker reputation in attracting savings.

[49] In each state, $0 < x_b^B < 1$, $x_b^{PC} > 0$, $n_b^{PC} > 0$, and $x_b^{PC} + n_b^{PC} < 1$. Internet Appendix B.2 gives the constrained conditions when these inequalities do not hold.

6.4 Why private credit requires scale

A bank that has not yet arranged private credit enters only if the fees from the additional savers it attracts cover the fixed cost. Let s_b^B and s_b^{PC} be its maximized market shares without and with access to private credit, holding rivals' portfolios fixed. These exact choices allow marginal-saver composition to adjust. Taking entry at indifference, the bank enters if and only if

$$f\left(s_b^{PC} - s_b^B\right) \geq F. \tag{28}$$

This exact comparison is the entry rule. For intuition, in the small-share case the share gain is approximately $\beta s_b g_b$, so to first order the bank enters when

$$f\,\beta\, s_b\, g_b \geq F \tag{29}$$

(Proposition B.2). Here βg_b is the approximate proportional increase in demand from offering the substitute. Multiplying it by the investor base s_b gives the additional savings attracted, and multiplying again by f gives the fee income available to cover F. For a given proportional demand response, a larger bank attracts more money and earns more fees, while paying the same fixed cost.

Less cautious savers accept more risk in exchange for yield, making the substitute more valuable to the small bank's marginal savers. However, the larger bank can offer it to a broader investor base. Under the scale condition, that broader base dominates, and its additional fee income is greater.[50] For an intermediate fixed cost, only the large local bank enters. The small bank also wants to offer higher returns, but doing so through private credit would cost more than the additional fees it earns. Launching a new product does not remove this bank-level cost. Figure 8 illustrates the resulting entry threshold.

[50] For the small-share, first-order gain, Proposition B.2 gives the sufficient condition $\mathrm{Var}_b(\gamma)(1+\beta R_b) < \bar{\gamma}_b^2$ along the reputation comparison, which we call the scale condition. It allows the bond portfolio to adjust and ensures that the investor-base effect outweighs the change in marginal savers' preferences. The numerical example checks the exact fee gains directly.

6.5 Debt resolution and the three predictions

We represent the persistent loss of bond income by a fall in expected excess return from μ_B to $(1-\tau)\mu_B$, with $0 < \tau < 1$. To isolate this yield channel, the benchmark holds private credit returns, asset risks, and marginal-saver composition fixed. Expected returns are net of credit losses, and the contractual-yield evidence motivates only the direction of the shock. The predictions use the sorting, scale, and interior-portfolio conditions above, and Internet Appendix B also allows bond risk to fall and solves a numerical equilibrium with changing saver composition. Throughout, Δ denotes the post-resolution change.

Prediction 1: smaller banks rely more on higher-yielding local bonds. Before entry into private credit, the optimal bond share and its response to reputation are

$$x_b^B = \frac{\mu_B}{\bar{\gamma}_b \sigma_B^2}, \qquad \frac{dx_b^B}{da_b} = -\frac{\mu_B}{\bar{\gamma}_b^2 \sigma_B^2} \frac{d\bar{\gamma}_b}{da_b} < 0. \tag{30}$$

Under the sorting and scale conditions, higher reputation raises marginal risk aversion, $d\bar{\gamma}_b/da_b > 0$, and lowers the optimal bond share. Smaller banks instead use more bond yield to attract their less cautious savers. Prior entry into private credit further reduces bond holdings through equation (24). Table 1 examines the predicted all-bank size gradient, and Table 2 establishes that local banks pursue this strategy mainly through home borrowers.

Prediction 2: scale determines which banks substitute into private credit. For a first-time entrant, the small-share, first-order entry benchmark gives

$$\begin{aligned} n_b^* &= \mathbb{1}\left\{ s_b/\bar{\gamma}_b \geq C(\tau) \right\} n_b^{PC}, \\ C(\tau) &= \frac{2F\left(\sigma_{PC}^2 - \sigma_{B,PC}^2/\sigma_B^2\right)}{f\beta\left[\mu_{PC} - (\sigma_{B,PC}/\sigma_B^2)(1-\tau)\mu_B\right]^2}. \end{aligned} \tag{31}$$

Here s_b is the bond-only market share at the comparison date, and n_b^{PC} is the conditional position in equation (24) at the lower bond return. As τ rises, private credit becomes more valuable relative to bonds and the entry cutoff $C(\tau)$ falls. Under the scale condition, the large

local bank can cross this cutoff while the small bank remains below it. Earlier users do not pay again: they expand n_b^{PC} as bonds become less attractive, with the positive response derived in equation (B.17). The allocation tests measure expansion across size groups, combining existing users and new participants (Tables 8 and 9), and the difference also appears in freshly chosen portfolios (Table 10).

Prediction 3: smaller local banks lose more product return and savings business. Comparing the two initially bond-only local banks when only the large bank enters,

$$\begin{aligned}\Delta R_L - \Delta R_S = \tau(2-\tau)\frac{\mu_B^2}{\sigma_B^2}\left(\frac{1}{\bar{\gamma}_S} - \frac{1}{\bar{\gamma}_L}\right) \\ + \left(\mu_{PC} - \frac{\sigma_{B,PC}}{\sigma_B^2}(1-\tau)\mu_B\right)n_L^{PC} > 0.\end{aligned} \tag{32}$$

The smaller bank loses more bond income because it relied more on bonds before resolution, which is the first term. Only the larger bank replaces part of that income with private credit, which is the second. The small bank therefore loses part of the return advantage it used to compete against the larger bank's reputation. In the small-share benchmark, holding the national bank's offer fixed, this deterioration in its relative offer also reduces its relative share of savings (Proposition B.5). We examine the return implications using initial bond exposure (Table E5), private-credit expansion (Table 12, Panel A), and bank size (Table 9). The business comparisons relate initial exposure and expansion to balances in newly launched WMPs (Table 12) and bank size to total WMP balances (Table 11). Figures 6 and 7 trace the size-related differences over time.

7 Conclusion

In China's WMP market, LGFV bonds did more than finance local public projects: they gave smaller banks a source of yield with which to compete against larger rivals. The 2023 debt resolution eroded this advantage. LGFV bond spreads compressed, and the estimated

product-return premium associated with home LGFV holdings fell by 69%. Private credit retained higher contractual yields and a positive product-return premium.

Larger local banks expanded private credit, largely within the LGFV sector, while smaller banks made little use of it even in newly launched products. Replacing bond yield thus involved a shift toward more opaque financing within the local LGFV sector, concentrated at larger institutions.

Greater initial home LGFV exposure predicted larger return losses and weaker fundraising through newly launched WMPs, measured by their balances. Greater private-credit expansion was associated with better return preservation and stronger fundraising, conditional on initial portfolios and bank size. The additional size coefficients are statistically insignificant in these joint regressions. Smaller banks nevertheless lost ground in product returns and total WMP balances in the separate size comparisons. Taken together, the evidence ties smaller banks' disadvantage to their reliance on lost bond yield and their limited substitution, rather than to size as such.

The model explains why greater reliance on yield need not bring a greater ability to replace it. Smaller banks compete more heavily on returns because reputation draws cautious savers toward larger rivals. Yet the fixed cost of establishing private credit is worthwhile only when the additional savings generate enough fee income. This separates the need for a substitute from the scale needed to use it. Government support for borrowers can consequently reshape competition among the intermediaries financing them: when the available substitutes require scale, stabilization can erode smaller banks' competitive edge and shift shadow banking toward larger institutions and more opaque credit.

Notes: PC denotes private credit. This table tests whether local banks overweight home credit beyond what provincial market size predicts. Estimates use equation (2). The unit of observation is a product-quarter. The dependent variable is the product's home-province share within the asset class minus the home province's share of nationwide disclosed holdings in the class, Within-category home bias$^{n}_{iq}$, as a fraction. Each column uses products with positive holdings in the class. All credit pools all included debt, and the LGFV, PC, and Other standard columns restrict it to LGFV bonds, private credit, and other bonds not issued by LGFVs. Local bank equals one for products of banks other than state-owned and joint-stock commercial banks. Product size and the number of disclosed positions enter as $\log(1+x)$. Total disclosed weight is the sum of the disclosed positions' reported portfolio weights. Average product maturity and average product risk rating are the average contractual term and numerical risk rating of the bank's products in the quarter, weighted by holding records. Standard errors clustered at the bank-city-by-quarter level are in parentheses. *, **, and *** denote significance at the 10%, 5%, and 1% levels. Estimation sample: 2022Q1–2025Q3.

Table 3

		(0.684)
Observations	554,555	554,555
Month fixed effects	Yes	Yes
Standard errors	Parent bank	Parent bank

Notes: Monthly log adjusted-NAV returns (bp) are regressed on all five lagged share levels, their Post interactions, and controls. Month effects absorb Post, which starts in October 2023. Column 1 uses product controls. Column 2 adds bank and home-city controls. Both use the column 2 sample. Shares are fractions. Non-home other bonds are the reference. Multiply coefficients by 0.2 for a 20-point allocation difference. Column 2's post-program premiums are 2.719 (SE 1.613) for home LGFV bonds and 4.370 (0.996) for home private credit. The difference in their premium changes is −3.738 (1.522). Centrally administered issuers are never home. Parentheses contain parent-bank clustered errors. Stars denote 10%, 5%, and 1% significance. Sample: Apr. 2022–Dec. 2025. See Internet Appendix E for robustness.

Table 4
Contractual-rate movements: private credit versus LGFV bonds

Panel A. Nationwide annual rate changes (pp)

Dependent variable	Borrowing yield (1)	PC yield (2)	Bond yield (3)
$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Year} = 2018\}$	-1.043^{***} (0.122)	—	—
$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Year} = 2019\}$	-0.171 (0.107)	—	—

$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Year} = 2024\}$	1.299^{***} (0.072)	—	—
$\mathbb{1}\{\text{Year} = 2018\}$	—	1.021^{***} (0.083)	2.085^{***} (0.086)
$\mathbb{1}\{\text{Year} = 2019\}$	—	1.107^{***} (0.097)	1.140^{***} (0.069)
$\mathbb{1}\{\text{Year} = 2020\}$	—	0.409^{***} (0.074)	0.453^{***} (0.045)
$\mathbb{1}\{\text{Year} = 2021\}$	—	0.033 (0.042)	0.611^{***} (0.031)
$\mathbb{1}\{\text{Year} = 2023\}$	—	-0.089^{**} (0.037)	0.163^{***} (0.033)
$\mathbb{1}\{\text{Year} = 2024\}$	—	-0.245^{***} (0.053)	-1.436^{***} (0.042)
Observations	102,310	36,251	27,769
Issuer × quarter fixed effects	Yes	No	No
Issuer × debt type fixed effects	Yes	No	No
Maturity category fixed effects	Yes	Yes	Yes
Borrower × creditor fixed effects	No	Yes	No
Issuer × bond type × placement fixed effects	No	No	Yes
Standard errors	Issuer	Issuer	Issuer

Notes: Each column is one regression of annual contractual borrowing yields (pp), using 2018–2024 observations. All estimated year coefficients are reported, 2022 is the reference. Column 1 pools private credit contracts and bond issues. Issuer-by-debt-type effects absorb the private-credit indicator, and issuer-by-quarter effects absorb year indicators. Its interactions therefore measure changes in the private-credit–bond yield gap relative to 2022. Columns 2–3 use one debt type each and estimate changes in its yield relative to 2022. The samples differ across columns, so their changes are not additive. The fixed effects and maturity controls follow Internet Appendix D.2. Parentheses contain issuer-clustered standard errors. Stars indicate 10%, 5%, and 1% significance.

Table 4 (continued)
Contractual-rate movements: private credit versus LGFV bonds

Panel B. Additional changes in priority provinces (pp)

Dependent variable	PC–bond gap (1)	PC yield (2)	Bond yield (3)
$\mathbb{1}\{\text{Priority province}\} \times \mathbb{1}\{\text{Year} = 2024\}$	1.042^{***}	0.317	-0.725^{***}
	(0.288)	(0.240)	(0.143)
$\mathbb{1}\{\text{Priority province}\} \times \mathbb{1}\{\text{Year} = 2023\}$	0.251	0.584^{***}	0.333^{***}
	(0.210)	(0.182)	(0.119)
Province wild p: 2024 gap	0.0063	—	—
Observations	2,296	2,296	2,296
Issuer fixed effects	Yes	Yes	Yes
Year fixed effects	Yes	Yes	Yes
Standard errors	Issuer	Issuer	Issuer

Notes: Each column is one regression on the same issuer-year sample, 2019–2024. Outcomes are annual contractual borrowing yields or their private-credit–bond gap (pp). Issuer effects absorb the priority-province indicator, and year effects absorb year indicators. Both estimated priority-province interactions, for 2023 and 2024, are reported, 2019–2022 form the pooled pre-program comparison. Each coefficient measures the additional change in priority provinces relative to other provinces. Because all columns use the same observations and regressors, column 1 equals column 2 minus column 3. Priority provinces are the twelve high-debt-risk provinces listed in Internet Appendix D.2. Parentheses contain issuer-clustered standard errors. Stars indicate 10%, 5%, and 1% significance.

Table 5
Prior reliance, refinancing intensity, and home LGFV allocation

Dependent variable	Home LGFV bond share (pp) (1)	Home LGFV bond share (pp) (2)	Home LGFV bond share (pp) (3)
Initial home overweight × refinancing intensity	−46.360*** (7.881)	−47.923*** (7.774)	—

Wild p: initial home overweight × refinancing	0.010	0.043	0.037
Observations	83,051	83,051	83,044
Initial home overweight × quarter indicators	No	Yes	Yes
Institution fixed effects	Yes	Yes	Yes
Home province × quarter fixed effects	Yes	Yes	Yes
Standard errors	Home province	Home province	Home province

Notes: Local-bank product-quarters. The outcome is the home LGFV share of included debt (pp). Initial home overweight is the initial benchmark-adjusted home allocation across all included debt, and intensity is cumulative refinancing divided by the bank's home province's 2020 LGFV debt. Both are fractions. Columns 2–3 include reliance-by-quarter slopes, not tabulated. Column 3 measures reliance through 2023Q2. Ordinary controls are displayed. Institution effects absorb initial home overweight, and home-province-by-quarter effects absorb refinancing intensity and common quarter indicators. Province-clustered errors are in parentheses. Wild tests use 27 provinces. Stars indicate 10%, 5%, and 1% significance. Estimation sample: 2022Q1–2025Q3.

Table 6
Home-province LGFV holdings after the program

Bank and city controls	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*
Bank × issuer city fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Bank × quarter fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Issuer city × quarter fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Standard errors	Bank city	Bank city	Bank city	Bank city	Bank city	Bank city

Notes: This table tests whether local buyers retreat relative to other buyers facing the same issuer-city bond supply. Estimates use equation (10). Bank-by-issuer-city effects absorb Home, Own city, Rest of home province, initial city risk, and Home × risk. Issuer-city-by-quarter effects absorb Post, the time trend, and Post × city risk. The remaining Home × Post term is reported alongside the triple interaction in column 5. The unit of observation is a bank, LGFV issuer city, and quarter over 2022Q1–2025Q3. The panel contains 73,635 cells in 248 issuer cities and covers the cities whose LGFV bonds a bank holds at some point, with zero holdings in quarters without positions in the city. Home equals one when a local bank invests in a city of its own province, and Post equals one from 2023Q4. Holdings are the bank's LGFV holdings in the city divided by its current bond book, its total WMP bond holdings in the quarter, in percentage points. Net holdings change includes changes in continuing positions as well as entries and exits, is divided by the current bond book, and is winsorized at the 1st and 99th percentiles. New purchases are the city's LGFV bonds that the bank holds in the quarter but did not hold a quarter earlier, entered as $\log(1 + \text{amount in RMB million})$. Column 2 separates the bank's own city from the rest of its home province. Column 5 interacts Home buyer × Post with the city's pre-program risk, the issue-size-weighted mean CSI spread of its LGFV bonds with maturities of one to five years over 2022Q3–2023Q2, in percentage points, for the 209 cities with at least five bond-quarter observations. The Home buyer × Post coefficient in that column is evaluated at a zero spread. Column 6 replaces Post with a linear quarterly trend and uses 2022Q1–2023Q3. Standard errors clustered by bank city are in parentheses. Clustering by issuer city or by bank-city pair gives standard errors of 0.151 and 0.146 in column 1. The mean holdings share in home cells is 3.91 before 2023Q4 and 3.43 afterward. Bank and destination-city characteristics are absorbed by the bank-by-quarter and city-by-quarter fixed effects. *, **, and *** denote significance at the 10%, 5%, and 1% levels. Estimation sample: 2022Q1–2025Q3 (columns 1, 2, 3, 4, 5), 2022Q1–2023Q3 (column 6).

Table 7
Private credit holdings by bank type and bank size

Asset category	National banks		Local banks	
	Pre	Post	Pre	Post
Panel A. Composition of included debt holdings, percent				
Home-province LGFV bonds	0.4	0.3	24.7	17.4
Home-province private credit	2.1	1.9	6.1	13.9
Private credit from other provinces	22.0	26.6	3.2	5.7
Product-quarters	34,595	59,691	36,194	57,516
Panel B. Share of the sector's holdings in local banks' products, percent				
Home-province private credit			61.6	83.1
All private credit			17.3	31.3
Home-province LGFV bonds			97.4	97.1
Panel C. Local banks present in both periods, by pre-program size tercile				
Home-province private credit, smallest tercile			0.72	0.31
Home-province private credit, middle tercile			3.45	4.74
Home-province private credit, largest tercile			7.45	18.26
Home-province LGFV bonds, smallest tercile			25.1	20.8
Home-province LGFV bonds, middle tercile			37.7	25.5
Home-province LGFV bonds, largest tercile			20.7	15.0

Notes: PC denotes private credit. This table locates the observed PC expansion by bank type, borrower geography, and local-bank size group. Product-quarter portfolios with positive included debt holdings, 2022Q1–2025Q3. Pre ends in 2023Q3. Post begins in 2023Q4. All panels use holding-value weights. Panels A and B retain all bank groups and classify Guangfa Bank, a nationwide joint-stock bank, and its subsidiary as national. Panel A reports class shares of each group's included debt holdings. Panel B reports the fraction of each category's holdings across all sample WMPs that local banks' products hold. Panel C retains underlying local banks observed in both periods. Groups are fixed by FY2021 interest-bearing assets, with common tercile cutoffs computed over the local banks in the Section 2 sample whose holdings are observed by 2023Q2. Bank financials are assigned to the bank's own products and those of its wealth-management subsidiary. Missing FY2021 size is not filled. Private credit includes trust loans, leasing and other identified private credit.

Table 8
Bank size groups and private-credit allocation

Dependent variable	Home PC share (pp) (1)	Total PC share (pp) (2)
𝟙{Middle tercile} × 𝟙{Post}	1.536	1.355
	(1.404)	(1.752)

Observations	85,181	85,181
Bank fixed effects	Yes	Yes
Quarter fixed effects	Yes	Yes
Standard errors	Parent bank	Parent bank

Notes: Each column is a product-quarter regression for local banks. Private-credit shares are percentages of included debt holdings, not total WMP assets. The omitted group is the smallest FY2021 bank-asset tercile. Groups follow Table 7. Post begins in 2023Q4. Bank effects absorb fixed group indicators and quarter effects absorb Post. Regressions use included debt value as weights, so the estimates describe the allocation of investment value. The displayed product, bank, and city controls include contemporaneous log bank assets. Parentheses contain bank-clustered standard errors. Stars denote 10%, 5%, and 1% significance. Internet Appendix D.9 gives complementary size comparisons. Sample: 2022Q1–2025Q3.

Home province × quarter fixed effects	Yes	Yes	No	Yes	Yes	No
Home province × month fixed effects	No	No	Yes	No	No	Yes
Standard errors	Bank city × quarter	Bank city × quarter	Bank city × month	Bank city × quarter	Bank city × quarter	Bank city × month

Notes: Each column is one regression for local-bank WMPs. Size is log FY2021 bank assets. Reliance is initial home overweight. Panel A interacts both with cumulative refinancing divided by the home province's 2020 LGFV debt. Panel B uses Post. Institution effects absorb size and reliance levels, and province-by-period effects absorb intensity or Post. All eleven controls are displayed. Allocation regressions use investment-value weights. Returns are unweighted. Errors cluster by bank-city-by-period. Underlying-bank clustering gives $p \leq 0.024$ for the size interactions. The return columns estimate pooled changes, not the quarter-specific differences relative to 2023Q3 in Figure 6. On the same observations, the pooled size–Post coefficient is 1.284 without reliance–Post and 1.234 with it. Section 5.6 reconciles this comparison with the figure. Stars denote 10%, 5%, and 1% significance. Samples end in 2025Q3 and start in 2022Q1 for allocations and 2022Q2 for returns.

Table 10
Private credit in new products, by bank size

First eligible portfolio	Smallest tercile	Middle tercile	Largest tercile
New products	253	1,877	5,248
Products holding home private credit	2	108	1,118
Products holding any private credit	2	134	1,586
Home private credit share (%)	0.78	6.31	27.46
Non-home private credit share (%)	0.00	2.73	14.74
Total private credit share (%)	0.78	9.04	42.20
Home LGFV bond share (%)	29.36	27.94	11.11
Home private credit share: first disclosure within one quarter (%)	0.59	5.75	27.29
Products in that restriction	234	1,737	4,611

Notes: PC denotes private credit. This table compares the first observed portfolios of products launched after the program by local banks in each size tercile. Launches in 2023Q4–2025Q3 are identified from income-start dates, when products begin accruing returns, rather than first disclosure, and each product contributes its first eligible portfolio, the first disclosed portfolio with positive included debt holdings. Shares are holding-value weighted percentages of included debt holdings. Counts are unweighted. Size terciles use fixed FY2021 parent-bank interest-bearing assets and the common local-bank cutoffs. Products of a bank's wealth-management subsidiary are assigned to the parent bank. The final two rows restrict to products whose first portfolio is disclosed in the launch quarter or the next quarter. No regressions enter this table.

Table 11
Bank size and WMP business growth after the program

Dependent variable	Log WMP balance		
Specification	Baseline	Province–time	Size terciles
	(1)	(2)	(3)
Log bank size × 𝟙{Post}	0.152***	0.144***	—
	(0.039)	(0.052)	
𝟙{Middle size tercile} × 𝟙{Post}	—	—	0.184*
			(0.093)
𝟙{Largest size tercile} × 𝟙{Post}	—	—	0.335***
			(0.088)
Wild-bootstrap p	< 0.001	0.008	< 0.001
Observations	571	494	571
Bank fixed effects	Yes	Yes	Yes
Half-year fixed effects	Yes	No	Yes
Home province × half-year fixed effects	No	Yes	No
Standard errors	Parent bank	Parent bank	Parent bank

Notes: Each column is one bank-half-year regression. Bank effects absorb fixed size and group indicators, and the time effects absorb Post. All columns use log positive observed WMP balances, combining the bank and subsidiary, with the source corrections described in Internet Appendix E.1. Size is unstandardized log FY2021 bank assets in RMB trillion. Post begins at year-end 2023. Column 1 includes bank and half-year effects. Column 2 replaces common half-year effects with home-province-by-half-year effects. Column 3 replaces continuous size with fixed size terciles interacted with Post, with the smallest tercile omitted. No additional controls enter. Missing reports are not zeros. Parentheses contain bank-clustered errors. Stars indicate 10%, 5%, and 1% significance. Internet Appendix E.1 discusses coverage. Estimation sample: 2022H1–2025H2.

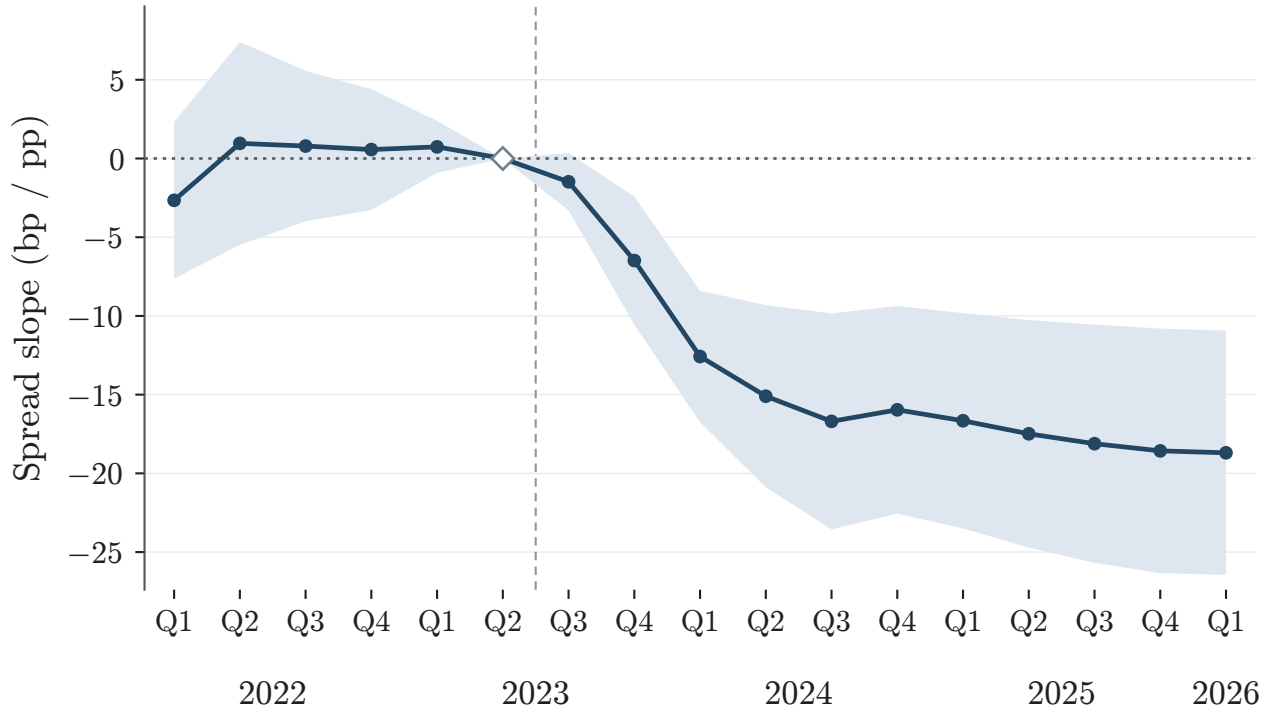

Table 12

Initial bond reliance, private-credit expansion, and WMP performance

Dependent variable	Panel A. Returns		Panel B. New-product balances	
	Monthly WMP return (bp)		Log total balances	
	No lagged controls	Add controls	Initial characteristics	Add PC expansion
	(1)	(2)	(3)	(4)
Initial home LGFV bond share × 𝟙{Post}	−10.685***	−13.172***	−1.556***	−1.662***
	(3.007)	(3.758)	(0.521)	(0.528)
Home private credit share increase × 𝟙{Post}	8.127*	9.189**	—	1.363**
	(4.488)	(4.376)		(0.630)
Log FY2021 bank size × 𝟙{Post}	1.128	0.298	0.224***	0.138
	(0.764)	(0.759)	(0.083)	(0.109)
Initial home private credit share × 𝟙{Post}	8.097*	6.956	0.823	1.547**
	(4.189)	(5.171)	(0.554)	(0.711)
Lagged log bank assets	—	−0.871	−0.213	−0.213
		(5.174)	(0.735)	(0.735)
Lagged nonperforming-loan ratio	—	−2.728	−0.459	−0.504*
		(2.319)	(0.285)	(0.285)
Lagged cost–income ratio	—	−0.435	−0.018	−0.010
		(0.274)	(0.032)	(0.032)
Lagged net interest margin	—	2.304	0.268	0.252
		(2.758)	(0.296)	(0.289)
Lagged city GDP (RMB trillion)	—	15.929**	1.554	1.697
		(6.210)	(1.037)	(1.025)
Lagged city GDP growth	—	−0.629*	−0.078	−0.080
		(0.352)	(0.051)	(0.052)
Lagged city LGFV debt/GDP	—	10.854	2.790***	3.033***
		(11.202)	(1.031)	(1.035)
Lagged urban income (RMB 10,000)	—	6.684**	0.919*	0.894*
		(3.341)	(0.496)	(0.488)
Observations	2,369	1,851	647	641
Bank fixed effects	Yes	Yes	Yes	Yes
Month fixed effects	Yes	Yes	No	No
Launch-quarter fixed effects	No	No	Yes	Yes
Standard errors	Bank	Bank	Bank	Bank

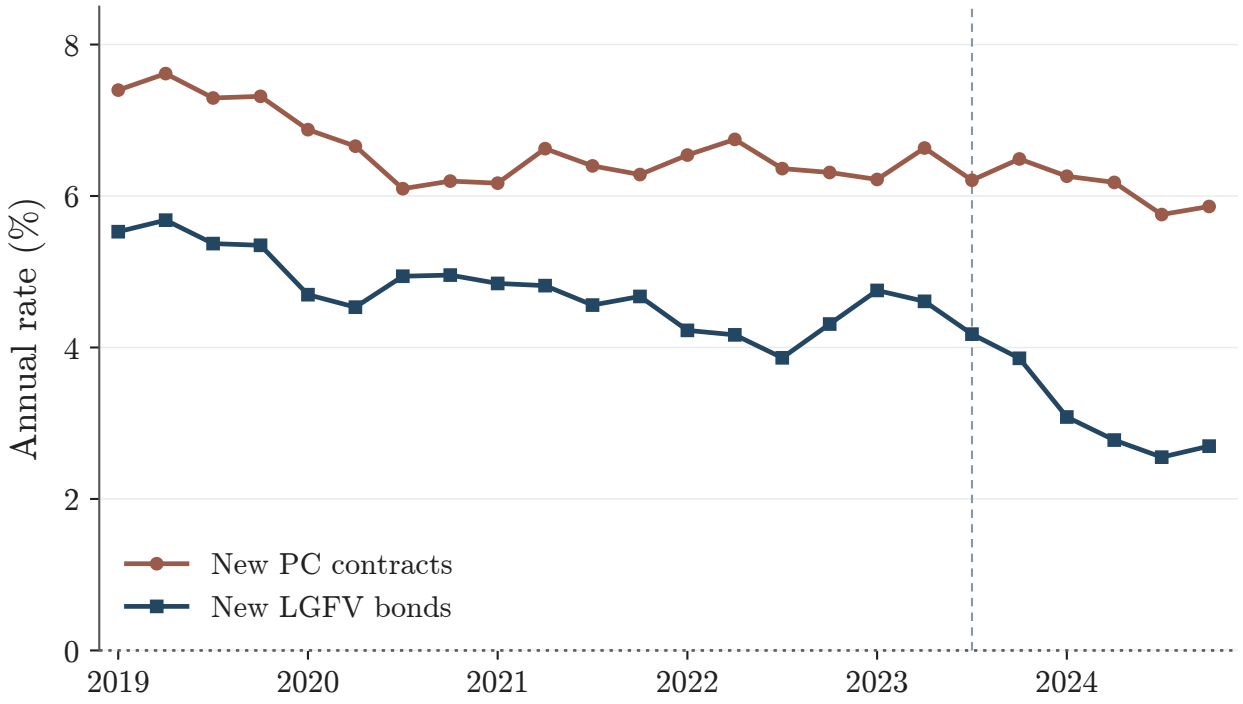

Notes: Each column is a separate regression. Panel A estimates equation (12) for bank-average monthly WMP log returns. Column 1 omits the eight lagged controls. Panel B estimates equation (13) for log total balances in products launched by a local bank in a quarter. Column 3 omits the private-credit-expansion interaction. Columns 2 and 4 report the full specifications. Each new product's balance is measured at the end of the following quarter, and balances are summed before taking logs. Initial portfolio shares use 2022Q1–2023Q2 holdings, and expansion is the change in the mean quarterly home private-credit share from that window to 2023Q4–2025Q3. Shares are raw fractions of included debt holdings. Size is log FY2021 bank interest-bearing assets. All slope coefficients are shown. Bank effects absorb the bank-characteristic levels, and time effects absorb Post. Controls lag one quarter. Returns cover July 2022–September 2025. Launches cover 2022Q2–2025Q2. Both omit 2023Q3, and Post begins in 2023Q4. Columns 3–4 cover 13,182 and 13,100 products. Each outcome uses its full eligible sample with equal bank-month or bank–launch-quarter weights. The two panels are not a common-sample comparison. Unobserved cohorts are not zeros. Parentheses contain bank-clustered standard errors. Stars denote 10%, 5%, and 1% significance. Internet Appendices E.4 and E.5 explain the construction.

Figure 1
Provincial LGFV spreads by final refinancing intensity

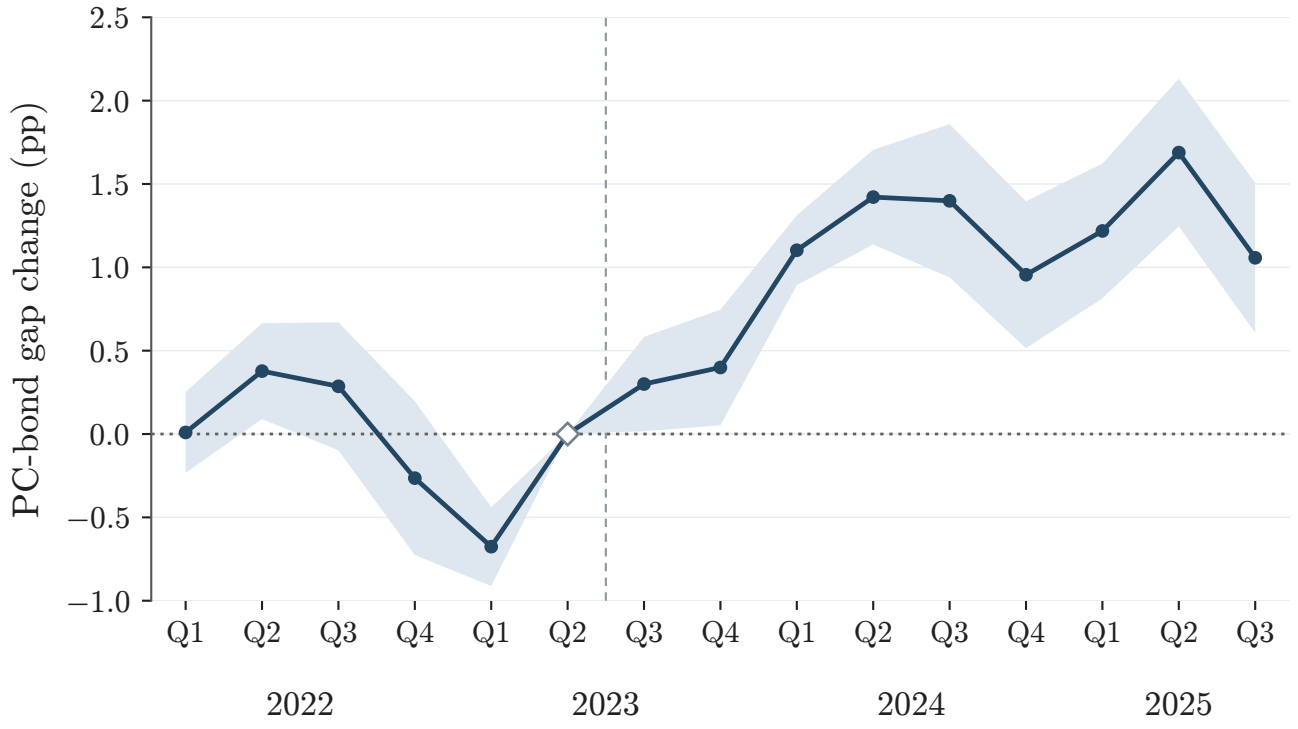

Notes: This event study plots the quarter-specific coefficients β_k in equation (D.1). Provincial LGFV secondary-market spreads, in basis points, are regressed on final refinancing intensity interacted with quarter indicators, with province and quarter fixed effects and 2023Q2 as the omitted quarter. Final intensity is cumulative special-refinancing issuance at the end of the intensity series as a percentage of 2020 provincial GDP. Coefficients are basis points per percentage point of final intensity, without standardization. Spreads and intensity are winsorized at the 1st and 99th percentiles, and the sample covers 31 provinces over 2022Q1–2026Q1. The shaded bands are pointwise 95% confidence intervals based on standard errors clustered by province, and the dashed line marks 2023Q3.

Figure 2
Contractual rates on new LGFV financing

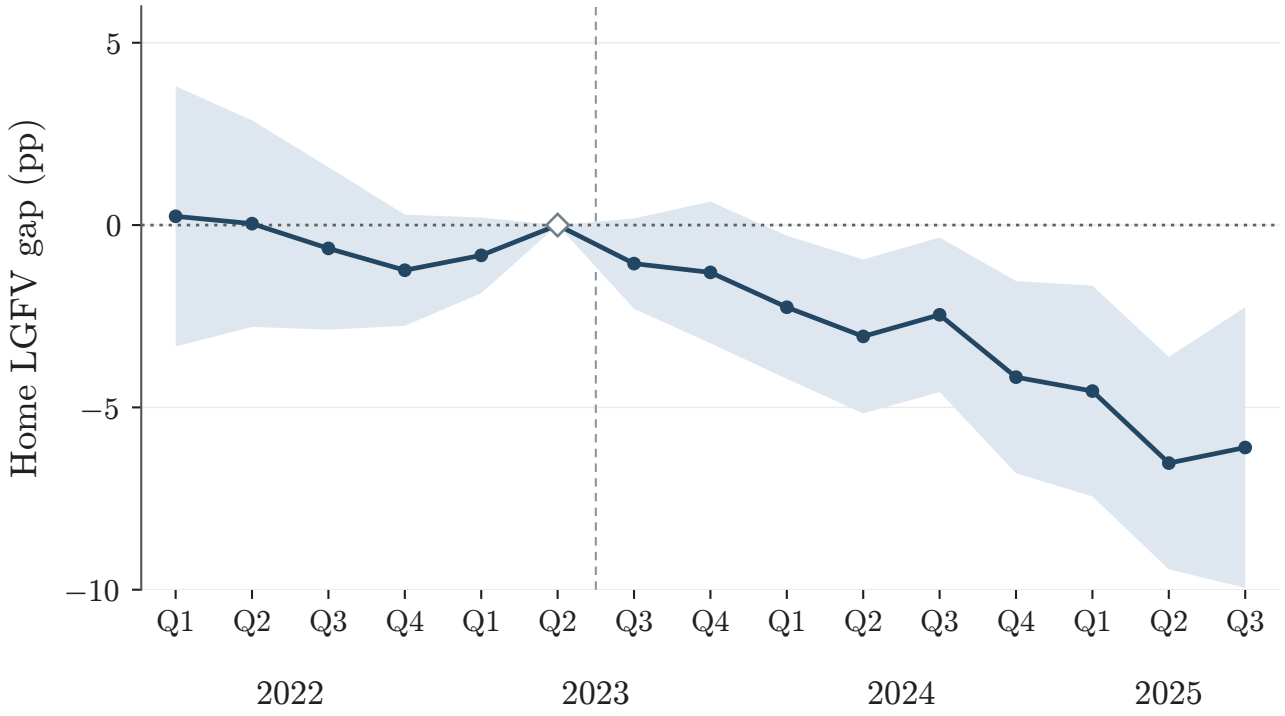

Notes: PC denotes private credit. This figure compares financing-yield opportunities in private credit and LGFV bonds. The series are quarterly annual contractual yields, in percent, on new PC contracts and new LGFV bond issues, 2019Q1–2024Q4. Each series uses financing reported by LGFV issuers in the deduplicated financing records and weights rate-visible observations by positive known original financing amounts. Unknown amounts are not imputed. The series need not contain the same borrowers in a quarter and are not adjusted for changes in composition or tenor. The dashed vertical line marks the 2023Q3 announcement. Table 4 compares rates within issuers and controls for tenor. Incomplete 2025 observations are excluded.

Figure 3
The private credit–bond rate gap within the same borrower

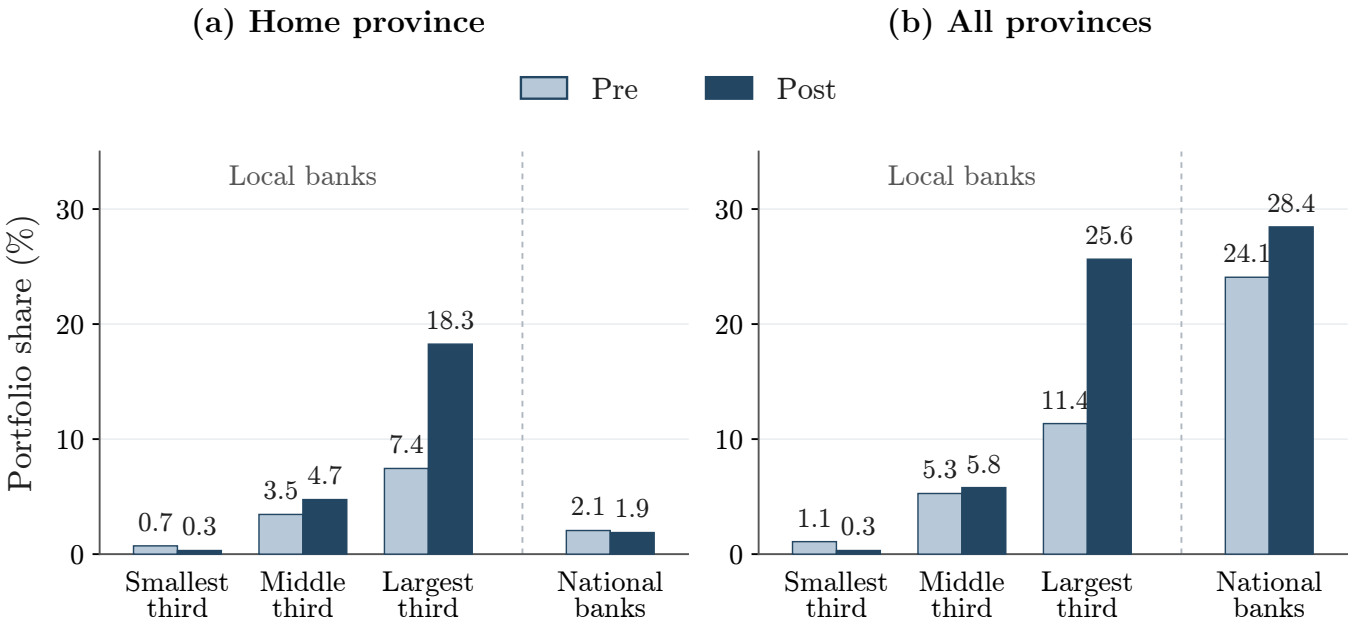

Notes: This within-borrower event study plots $\delta_q = \beta_q - \beta_{2023Q2}$ as defined in equation (8): changes in the annual contractual PC-minus-bond rate gap, in percentage points. Quarterly gap levels are estimated by equation (7), with borrower-by-calendar-month effects and continuous maturity interacted with every quarter. There are no borrower-by-debt-type effects. The plot starts in 2022Q1. The usable estimation sample is 2021Q1–2025Q3 (17,303 financing observations, 589 borrowers), with observed maturity required and fixed-effect singletons removed. The funded borrower's entity identifier must equal the reporting issuer's. Affiliates are excluded. Before these restrictions, the pool contains borrower-quarters with both channels and borrowers with at least two matched quarters. Observations are equally weighted. Shading gives conventional pointwise 95% confidence intervals clustered by borrower province, using t_{25} critical values (26 provinces) and the covariance of the gap contrasts. The hollow diamond marks the reference. The vertical dashed line separates 2023Q2 from 2023Q3. Coverage falls to 58, 35, and 21 borrowers in 2025Q1–Q3, and 19 borrowers have both channels in the same month in 2025Q3. No usable 2025Q4 comparison remains. Earlier changes, 2021Q1–2023Q1, reject joint zero ($p < 0.001$). Tables D4–D5 report specification, inference, and coverage checks.

Figure 4
Home-province gap in local banks' LGFV holdings by quarter

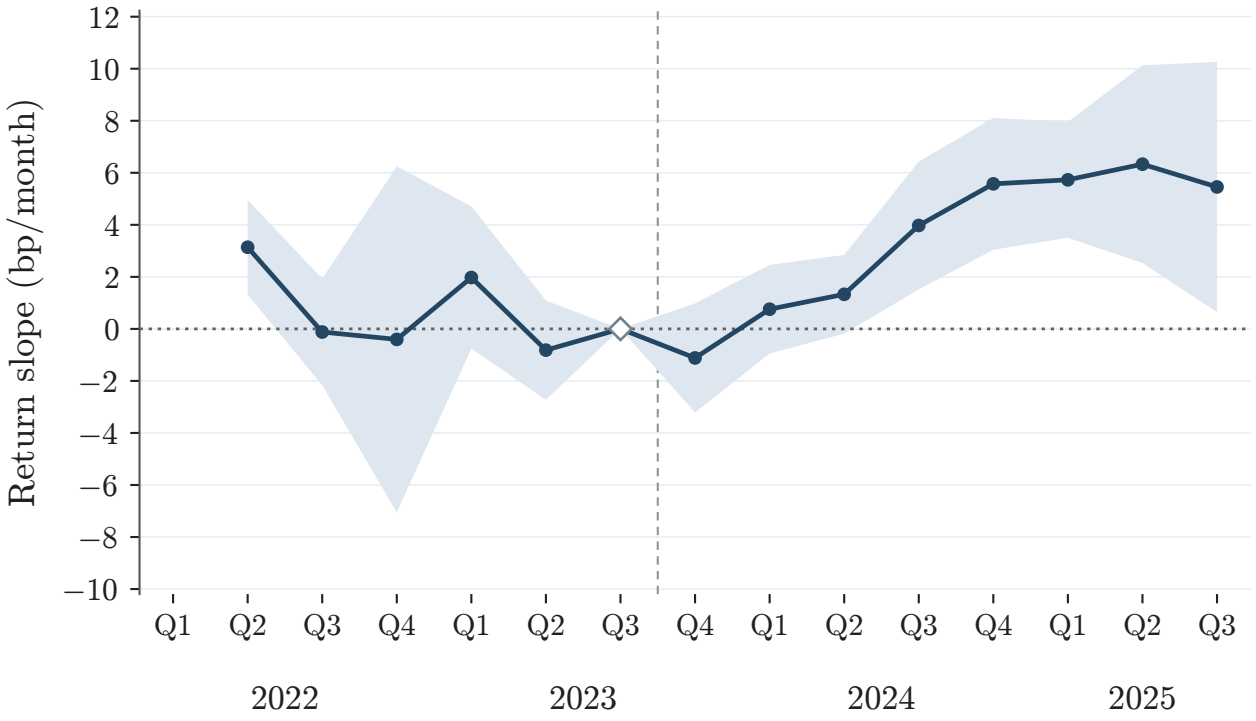

Notes: This event study plots the home-bond allocation coefficients η_k in equation (D.6). A buying institution's LGFV holdings in a province, as a percentage of its total bond holdings and winsorized at the 1st and 99th percentiles, are regressed on Home interacted with quarter indicators. Buyer-by-province, buyer-by-quarter, and destination-province-by-quarter fixed effects enter, and 2023Q2 is omitted. The sample covers 2022Q1–2025Q3. The observation is a buyer, province, and quarter, so the coefficients measure changes in the home gap for an entire province rather than a single city as in Table 6. Home equals one for a local bank's own province. The shaded bands are pointwise 95% confidence intervals based on standard errors clustered by bank city, and the dashed line marks 2023Q3.

Figure 5
Private credit allocation before and after implementation

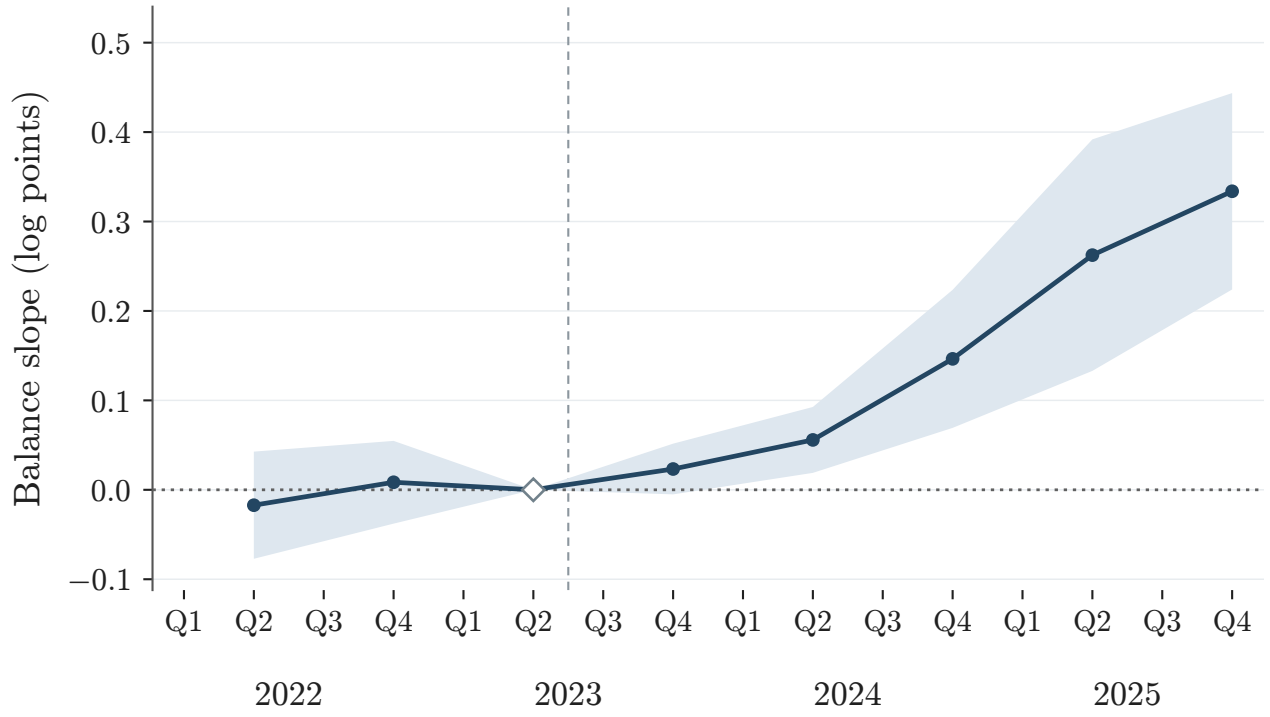

Notes: Bars are descriptive, holding-value-weighted portfolio shares. Both panels divide private credit by the included debt holdings defined in Table 7. Panel (b) includes home and non-home private credit. Pre covers 2022Q1–2023Q3 and Post covers 2023Q4–2025Q3. Local-bank terciles use fixed FY2021 underlying-bank interest-bearing assets and retain the same banks in both periods. The national-bank comparison uses the national banks in Table 7, Panel A. Home is the underlying bank's headquarters province.

Figure 6
Bank size and product returns by quarter

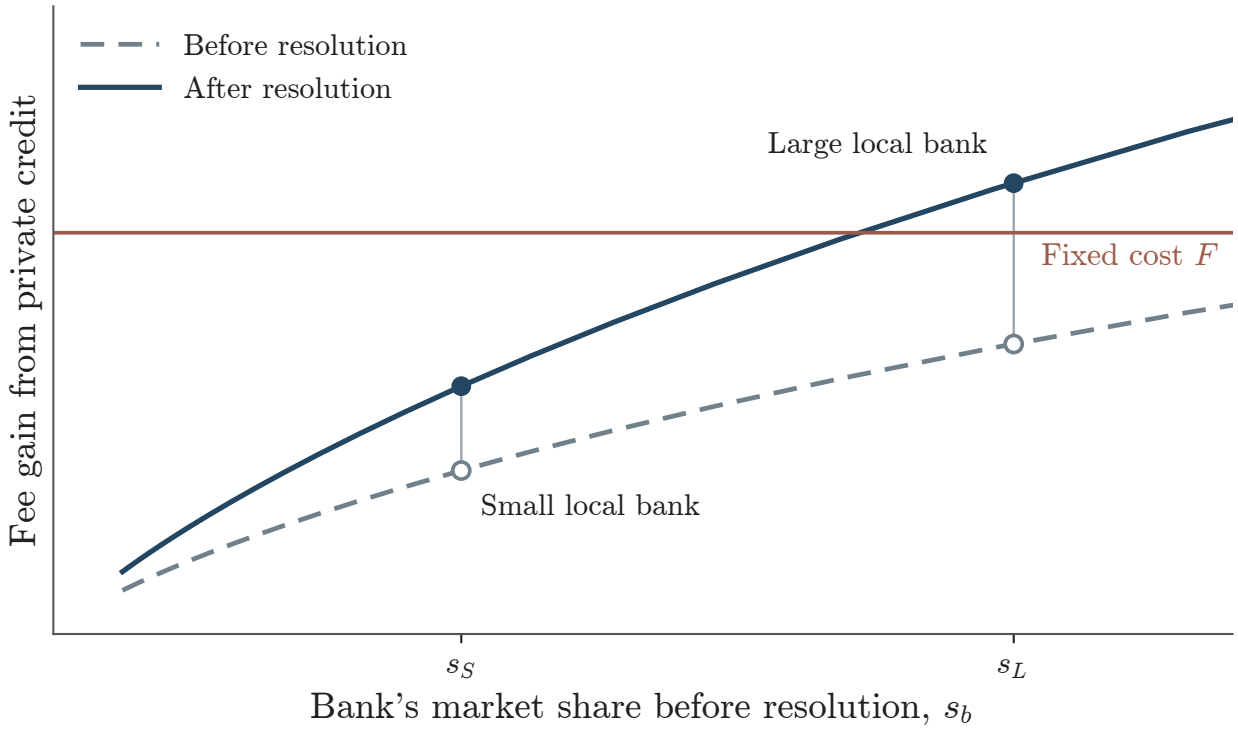

Notes: This event study replaces both refinancing interactions in equation (14) with log bank size interacted with quarter indicators. The outcome is monthly log adjusted-NAV return (bp) for local-bank products. Each coefficient measures the change in the size–return slope relative to 2023Q3, per log point of FY2021 underlying-bank interest-bearing assets in RMB trillion, without standardization. The regression includes the eleven time-varying controls, institution effects, and bank-home-province-by-month effects, but no prior-reliance interactions. The sample is 2022Q2–2025Q3 (206,770 NAV-series-months). Shading shows pointwise 95% confidence intervals based on underlying-bank clustered errors. The hollow diamond marks the normalized reference quarter, not an estimated zero. The vertical line marks implementation in 2023Q4.

Figure 7
Bank size and total WMP balances

Notes: This event study replaces the size–Post interaction in equation (15) with log bank size interacted with half-year reporting-date indicators. The quarterly axis locates actual midyear and year-end reports at Q2 and Q4. No Q1 or Q3 balances are imputed. The log-balance regression includes bank and half-year fixed effects and no additional controls, for local banks over 2022H1–2025H2 (571 bank-half-years). Each coefficient measures the change in the size–balance slope relative to the June 2023 report (2023Q2), per log point of FY2021 interest-bearing assets in RMB trillion, without standardization. Balances combine a bank's own products and those of its wealth-management subsidiary. Shading shows pointwise 95% confidence intervals based on bank-clustered errors. The hollow diamond marks the reference. The vertical line separates 2023Q2 and Q3. The joint test that the two 2022 coefficients are zero has a p-value of 0.094. Source: Wind institution-level WMP statistics, with the bank-disclosure corrections described in Internet Appendix E.1.

Figure 8
The scale threshold for private credit

Notes: This figure illustrates the entry condition in equation (28), using the parameters and equilibrium portfolios in Internet Appendix B.6. The curves vary the reputation of an additional bank facing those portfolios and plot its optimized fee gain before resolution (dashed) and afterward (solid), against its bond-only market share before resolution. Entry is worthwhile when the gain covers F. The circles evaluate these curves at the small and large local banks' pre-resolution market shares. Only the large bank's gain crosses the threshold. Table B1 reports the exact gains for the three equilibrium banks.

Internet Appendix

How Hidden Local Government Debt Shapes Shadow Banking Competition: Evidence from Wealth Management in China

The appendix contains supporting exhibits (Internet Appendix A), the model solution and proofs (Internet Appendices B and C), specifications and supplementary results (Internet Appendix D), and measurement and mechanism checks (Internet Appendix E).

Internet Appendix A Supporting Evidence

A.1. Data, investment opportunities, and portfolio denominators

Table A1 defines the variables, Table A2 reports sample coverage, and Table A3 summarizes products, holdings, and issuers. Figure A1 compares WMPs with other Chinese asset-management products and shows their 2025 asset mix, and Figure A2 traces WMP balances since 2013.

Table A14 compares LGFV issuance yields with those of other issuers. Across 20,172 unique RMB fixed-rate bonds issued at par in 2022Q1–2023Q3, LGFV yields exceed other nonfinancial and financial issuers' yields by 122 and 149 basis points. Controlling for issue month, maturity, issue size, and call provisions leaves gaps of 91 and 108 basis points, and adding ratings gives 88 and 110.

Table A10 reports disclosed holdings by value, portfolio weight, and number of positions. LGFV bonds account for 16.4% of local banks' reported portfolio weights, compared with 5.4% at national banks, over 2022Q1–2025Q3. These shares of all disclosed assets are smaller than the shares of included debt holdings in Section 3.1. Appendix D.8 reconciles the denominators and explains the industry estimates in Figure A4.

A.2. Supporting estimates

Tables A5 and A6 report the redemption terms and home allocations discussed in Section 3.2. Table A7 relates home LGFV exposure to returns, volatility, and downside outcomes (Section 3.3), and Table A9 relates relative performance to subsequent investor flows (Section 3.4). The pricing, distress, and maturity-wall estimates of Section 3.5 are in Tables A11, A12, and A8. Figure A3 shows provincial spread convergence, and Table A4 relates spreads to cumulative refinancing relative to GDP. Appendices D.2–D.7 give the designs.

In Table A13, the size–Post coefficient for the combined home allocation of LGFV bonds and private credit is 4.76 percentage points per log point of bank assets, or 3.3 points for a doubling. Larger banks therefore kept more of their investment in home borrowers.

Table A1
Variable definitions

Variable	Definition
$\mathbb{1}\{\text{Local bank}\}_b$	One for banks other than state-owned and nationwide joint-stock banks.
Within-category home bias$^n_{iq}$	Home holdings / all holdings within class n, minus the home province's share of nationwide class-n holdings. Requires positive class holdings (equation (2)).
Portfolio home overweight$^n_{iq}$	Home class-n holdings / all included debt holdings, minus nationwide investment in class n in the home province / nationwide included debt holdings. Includes products holding none of class n. Without n, it sums across classes (equation (D.12)).
Initial home overweight$_a$	Product-assets-weighted pre-program mean of portfolio home overweight for issuing institution a, 2022Q1–2023Q3.
Log bank size$_b$	Natural log of FY2021 underlying-bank interest-bearing assets (RMB trillion), without standardization.
Initial home LGFV share$_b$	Home LGFV bonds / included debt holdings, holding-value weighted over 2022Q1–2023Q2, without subtracting market weights.
$\mathbb{1}\{\text{Restricted redemption}\}_i$	One for products without daily redemption.
Monthly return	Log return computed from month-end adjusted NAVs in consecutive months, in basis points.
Trailing volatility	Annualized standard deviation of monthly returns over the twelve months ending in the outcome month.
Net flow$_{iq}$	Quarterly net flow: growth in inferred assets net of returns, in percent (equation (D.9)).
Yield concession$_{jq}$	CSI valuation spread minus coupon-based issue spread, converted from percentage points to basis points.
Same-city purchase share$_{jq}$	WMP holdings of bond j first disclosed in its issue quarter q by local banks in the issuer's city, divided by total issue size and multiplied by 100, a proxy for their issuance purchases.
Other-city purchase share$_{jq}$	WMP holdings first disclosed in the issue quarter by local banks elsewhere in the issuer's province, divided by total issue size and multiplied by 100, a proxy for their issuance purchases.
Participating banks$_j$	Number of banks whose WMPs hold bond j in its issue quarter.
Total issue-quarter WMP share$_j$	WMP holdings of bond j in its issue quarter, in pp of issue size.
Issuer distress$_{jq}$	Equals 100 if the issuer records its first credit event within eight quarters after issuance, and zero otherwise.
$\mathbb{1}\{\text{Home buyer}\}_{ac}$	Equals one when issuing institution a is a local bank or its subsidiary and invests in issuer city c of the underlying bank's headquarters province.
Maturity wall$_{cq}$	Scheduled principal on all LGFV bonds maturing in city c and quarter q, as a percentage of 2020 city budget revenue.
Refinancing$^{GDP}_{pq}$	Cumulative special-refinancing issuance / 2020 provincial GDP (percentage points). Final refinancing$^{GDP}_p$ is its value at the last observed date.
Refinancing$^{debt}_{pq}$	Cumulative special-refinancing issuance / 2020 provincial LGFV debt (fraction), used for allocations and returns.
$\mathbb{1}\{\text{Post}\}$	Equals one from 2023Q4 in quarterly data and from October 2023 in monthly data.
Log WMP balances$_{bs}$	Log outstanding WMP balance of bank b at half-year end s, combining its own and its subsidiary's products.

Notes: Holdings cover 2022Q1–2025Q3. Included debt comprises bonds and identified private credit with known borrower locations, excluding central-government, central-bank, and policy-bank obligations. Issuer credit events include defaults, rating warnings, and guarantor events, not necessarily default on the held bond. Classes n are LGFV bonds, private credit (PC), and other standard (non-LGFV) bonds.

Table A2
Sample coverage

Panel A. Overall coverage

Measure	Count
Source holding records	2,288,894
Holding records with a usable product identifier	2,279,252
WMP products	60,396
Product-quarter observations	253,484
Bank headquarters provinces	30
Quarters	15

Panel B. Annual coverage

Year	Source holding records	WMP products
2022	421,072	19,514
2023	579,703	26,021
2024	708,907	30,512
2025 (Q1–Q3)	579,212	29,527

Panel C. Bank categories

Bank group	WMP products	Product-quarters
National banks	27,799	131,535
Large state-owned	9,571	49,593
Nationwide joint-stock	18,228	81,942
Local banks	32,597	121,949
Regional commercial	23,817	91,937
Rural institutions	8,780	30,012
All banks	60,396	253,484

Notes: Coverage is 2022Q1–2025Q3. A holding record is a product-asset-quarter observation. Source-record counts include 9,642 records with blank or "NA" product registration codes. Usable-record, product, and product-quarter counts exclude these codes. A parent-bank crosswalk groups wealth-management subsidiaries and alternative bank names with their underlying banks. Panel B counts products once per year, so annual counts need not sum to full-period counts. Panel C uses the source bank-type codes and assigns subsidiary products to the parent bank's category. Regional commercial banks include provincial and city-focused banks, which the source does not code as mutually exclusive geographic subgroups. Rural institutions include rural commercial and cooperative institutions. Guangfa Bank's wealth-management subsidiary is classified with nationwide joint-stock banks. Estimation samples impose the restrictions stated in each regression table.

Table A3
Descriptive statistics

Variable	Observations	Mean	SD	Median	p90
Panel A. Holding-observation characteristics					
Position weight (%)	2,286,025	7.12	12.03	4.04	11.46
Holding value (RMB million)	2,278,335	59.22	345.74	10.39	113.89
Panel B. Bond characteristics					
Issue yield (%)	1,162,002	4.09	1.19	4.00	5.58
Issue maturity (years)	1,162,491	5.09	3.06	5.00	10.00
Panel C. Additional bond-issue characteristics					
$\mathbb{1}\{\text{Guaranteed}\}$	57,429	0.10	0.30	0.00	1.00
$\mathbb{1}\{\text{Callable}\}$	57,429	0.09	0.29	0.00	0.00
Participating banks	57,429	0.23	0.52	0.00	1.00
Total issue-quarter WMP share (pp)	57,429	1.52	4.59	0.00	5.02
Panel D. Product-quarter characteristics in the NAV sample					
Log product assets	153,563	19.41	1.64	19.38	21.51
Product risk rating	153,563	2.15	0.44	2.00	3.00
Restricted redemption (0/1)	153,563	0.88	0.33	1.00	1.00
Panel E. Pre-implementation issuers' FY2021 assets (RMB billion)					
LGFV issuers	1,939	42.79	48.09	28.41	88.39
Other nonfinancial issuers	2,062	134.48	548.95	35.32	243.34
Financial issuers	570	525.79	2,765.50	52.90	560.29

Notes: Panel A describes holding records and Panel B bond holding records with the characteristic available. Panel C describes all 57,429 unique issues in the 2022Q1–2025Q4 bond database, before estimation restrictions and including issues without WMP ownership. Pricing regressions end in 2025Q3. Panel D counts each product-quarter in the return sample once. Log product assets is $\log(1 + \text{inferred assets in RMB})$, product risk is the numerical rating, and p90 is the 90th percentile. The cross-sectional SD of products' average monthly returns is 10.5 bp. Among local-bank product-quarters before October 2023, mean home and non-home LGFV bond shares of included debt are 0.263 (home p90: 0.722) and 0.180. Mean issue rates are 5.62% for home LGFV holdings and 4.93% for other-province holdings, and the mean within-product gap is 0.33 pp. Panel E separately describes firms issuing RMB debt in the available Wind issuance file over 2022Q1–2023Q3, not only WMP-held issues. Each issuer receives equal weight and appears once, matched by normalized exact name to reported year-end 2021 total assets. No future balance-sheet values are substituted. The LGFV roster identifies the first group, and source issuer types identify financial institutions and other enterprises. Central and local governments, policy banks, and unclassified issuers are excluded. Assets are observed for 1,939 of 1,964 LGFV issuers (98.7%), 2,062 of 2,167 other nonfinancial issuers (95.2%), and 570 of 723 financial issuers (78.8%).

Table A4
Refinancing intensity and provincial LGFV spreads

Trend controls	None	Pre-program spread trend	Province trends
Dependent variable	LGFV spread (bp)	LGFV spread (bp)	LGFV spread (bp)
	(1)	(2)	(3)
Refinancing / GDP (pp)	−17.665***	−2.434**	−8.652**
	(3.223)	(1.044)	(3.800)
Pre-program spread (bp) × linear trend	—	−0.0706***	—
		(0.0053)	
Mean of dependent variable	195.694	195.694	195.694
Observations	496	496	496
Province fixed effects	Yes	Yes	Yes
Quarter fixed effects	Yes	Yes	Yes
Province-specific trends	No	No	Yes
Standard errors	Province	Province	Province

Notes: This table tests whether provincial spread compression is greater where cumulative refinancing is more intensive. Province effects absorb the initial spread level, and quarter effects absorb the common linear trend. Estimates use equation (D.2). The unit of observation is a province-quarter. The dependent variable is the province's mean secondary-market LGFV spread in basis points. Refinancing intensity is cumulative special-refinancing issuance as a percentage of 2020 provincial GDP, without standardization. Spreads and intensity are winsorized at the 1st and 99th percentiles. Column 2 adds the 2022Q1–2023Q3 mean spread in basis points interacted with a linear quarterly trend, and column 3 includes a separate linear trend for each province. Standard errors clustered by province are in parentheses. *, **, and *** denote significance at the 10%, 5%, and 1% levels. Estimation sample: 2022Q1–2025Q4.

Table A5
Redemption terms by bank group

Institution group	Redemption	Product-quarter observations	Equal-weighted share (%)	Size-weighted share (%)
National banks	Daily	17,294	20.5	52.7
National banks	Non-daily	67,054	79.5	47.3
Local banks	Daily	2,376	2.8	19.8
Local banks	Non-daily	83,273	97.2	80.2

Notes: This table compares the redemption terms of local- and national-bank products. Entries report the number and share of product-quarters by bank group and redemption terms. Daily products allow redemption on every business day. Non-daily products, the restricted-redemption products in Table A6, are periodic-open or closed-end. Size-weighted shares weight product-quarters by inferred product assets. Shares sum to 100 within each bank group.

Table A6
Portfolio home overweight and redemption terms

Asset class	All credit	LGFV	PC	Other standard
Dependent variable	Portfolio home overweight (fraction) (1)	Portfolio home overweight (fraction) (2)	Portfolio home overweight (fraction) (3)	Portfolio home overweight (fraction) (4)

Observations	169,997	169,458	168,327	169,997
Quarter fixed effects	Yes	Yes	Yes	Yes
Standard errors	Bank city × quarter	Bank city × quarter	Bank city × quarter	Bank city × quarter

Notes: PC denotes private credit. This table tests whether restricted redemption is associated with a wider local–national home-credit gap. Estimates use equation (3). The unit of observation is a product-quarter. The dependent variable Portfolio home overweight$_{iq}^{n}$ is the product's home-province holdings of the asset class divided by the value of all its included debt holdings, minus the home province's holdings of the class as a share of nationwide included debt holdings, as a fraction. The first column pools all included debt holdings. Restricted redemption equals one for products without daily redemption, so the local-bank coefficient measures the difference between local and national banks among daily-open products and the interaction measures the additional difference among other products. All columns use the sample with nonmissing controls. Standard errors clustered at the bank-city-by-quarter level are in parentheses. *, **, and *** denote significance at the 10%, 5%, and 1% levels. Estimation sample: 2022Q1–2025Q3.

Table A7
Home LGFV exposure and product returns

Panel A. Monthly returns and volatility

Dependent variable	Monthly NAV return (bp) (1)	Trailing annualized volatility (bp) (2)
Home LGFV portfolio overweight (fraction)	3.140***	−11.150***
	(0.783)	(2.203)
𝟙{Local bank}	−0.076	5.279***
	(0.627)	(1.568)
Mean of dependent variable	23.873	75.758
Product, bank, and city controls	Yes	Yes
Observations	554,555	554,555
Month fixed effects	Yes	Yes
Standard errors	Bank city × month	Bank city × month

Panel B. Downside outcomes

Dependent variable	Monthly excess return (bp) (1)	Downside volatility (bp) (2)	Drawdown (log gap ×100) (3)	Negative return (0/1) (4)	Bottom-decile return (0/1) (5)	Drop over 50 bp (0/1) (6)
Home LGFV portfolio overweight (fraction)	3.817***	−6.942***	−0.061***	−0.039***	−0.039***	−0.008***
	(0.784)	(1.213)	(0.009)	(0.009)	(0.008)	(0.002)
𝟙{Local bank}	0.259	1.929**	0.009	0.012	0.006	−0.001
	(0.618)	(0.893)	(0.007)	(0.008)	(0.007)	(0.002)
Mean of dependent variable	0.271	24.489	0.088	0.099	0.092	0.015
Product, bank, and city controls	Yes	Yes	Yes	Yes	Yes	Yes
Observations	558,455	558,455	558,455	558,455	558,455	558,455
Month fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Standard errors	Bank city × month	Bank city × month	Bank city × month	Bank city × month	Bank city × month	Bank city × month

Notes: Each column estimates equation (D.10), retaining all eleven product, bank, and city controls. The exposure is home LGFV holdings as a fraction of included debt holdings, less the corresponding nationwide portfolio weight. Exposure and controls lag one quarter. Only exposure and local-bank coefficients are displayed. Panel A uses the common return–volatility sample, excluding observations outside either variable's 1st–99th percentiles. Panel B uses a separate common sample: excess return subtracts the mean for the same redemption type, downside volatility uses negative monthly returns, and drawdown is 100 times the trailing-peak minus current log NAV. The last three outcomes are indicators, so coefficients are probability changes. Volatility measures are annualized over up to twelve months, requiring two observations. Appendix D.6 gives the complete definitions. The sample is 2022Q2–2025Q4. Parentheses contain bank-city-by-month clustered standard errors, and stars denote 10%, 5%, and 1% significance.

Table A8
Refinancing pressure and home-province allocation

Panel A. Allocation margins

Dependent variable	Log(1 + new purchases)	New purchases (%)	Net purchases (%)	1{Buy}	Exits (%)	Holdings (%)
	(1)	(2)	(3)	(4)	(5)	(6)
1{Home buyer} × maturity wall	0.00011	−0.00088	−0.0070***	0.00053	0.0045***	−0.0087*
	(0.00218)	(0.00120)	(0.0018)	(0.00046)	(0.0013)	(0.0046)
Mean of dependent variable	0.937	0.120	−0.023	0.261	0.155	0.671
Observations	73,127	73,089	66,013	73,127	66,013	73,089
Bank and city controls	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*
Bank × issuer city fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Bank × quarter fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Issuer city × quarter fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Standard errors	Bank city	Bank city	Bank city	Bank city	Bank city	Bank city

Notes: Bank–issuer-city–quarter regressions. Bank-by-issuer-city effects absorb Home, and issuer-city-by-quarter effects absorb the maturity wall. Home denotes a local bank investing in its own province. The wall is scheduled principal on all city LGFV bonds maturing in the quarter as a percentage of 2020 city budget revenue. Holdings and new purchases are percentages of the buyer's current bond holdings, and net purchases and exits of its previous-quarter bond holdings. Log new purchases use RMB million. The Buy indicator equals one for any new purchase. Net buying removes valuation changes, and exits include nonrenewal. Parentheses contain bank-city clustered errors. Appendix D.4 describes the sample. Stars indicate 10%, 5%, and 1% significance. Estimation samples: Panel A, 2022Q1–2025Q3 (columns 1, 2, 4, 6), 2022Q2–2025Q3 (columns 3, 5). Panel B, 2022Q1–2025Q3.

Panel B. Characteristics of purchased bonds

Dependent variable	Issuer rating (1–4)	1{Guaranteed}	Maturity (years)	Issue spread (pp)	Log issue amount
	(1)	(2)	(3)	(4)	(5)
1{Home buyer}	−0.1972***	0.0389**	−0.0676	0.1507***	−0.0901***
	(0.0316)	(0.0172)	(0.0599)	(0.0454)	(0.0254)
1{Home buyer} × maturity wall	0.00119*	0.00116**	0.0027*	−0.00040	0.000042
	(0.00060)	(0.00046)	(0.0014)	(0.00080)	(0.000512)
Mean of dependent variable	2.8405	0.1540	3.6470	1.6174	2.0001
Observations	33,209	36,303	36,303	36,303	36,303
Bank and city controls	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*	*Absorbed*
Bank × quarter fixed effects	Yes	Yes	Yes	Yes	Yes
Issuer city × quarter fixed effects	Yes	Yes	Yes	Yes	Yes
Standard errors	Bank city	Bank city	Bank city	Bank city	Bank city

Notes: New bond purchases. Outcomes are characteristics of the bonds purchased, not of their issuer cities. The regressions include the Home indicator and its wall interaction. Issuer-city-by-quarter effects absorb the wall level. Bank-by-quarter effects also enter, but bank-by-issuer-city effects do not. The wall has the same percentage-point definition as in Panel A, and neither panel standardizes it. Issuer ratings run from 1 (AA− or below) to 4 (AAA). Issue spreads are over Treasury yields, in percentage points, and guarantees are indicators. Parentheses contain bank-city clustered errors. Stars indicate 10%, 5%, and 1% significance.

Table A9
Relative performance and subsequent investor flows

Category × quarter fixed effects	Yes	Yes	Yes	Yes
Home province × quarter fixed effects	No	Yes	No	No
Standard errors	Parent bank	Parent bank	Parent bank	Parent bank

Notes: Each column is one regression of next-quarter flows on prior-quarter return fifths within risk and redemption categories, with the bottom fifth omitted. Controls are displayed and dated before flows. Category-by-outcome-quarter effects enter, and column 2 adds home-province-by-quarter effects. Parentheses contain parent-bank clustered errors, and the wild-bootstrap p is for the top-fifth coefficient. Net flows in columns 1 and 2 are capped at the 1st and 99th percentiles. Symmetric flows are bounded between −200 and 200 and uncapped, and positive flow is 100 times an indicator of net inflow. Appendix D.5 defines the measures. Stars indicate 10%, 5%, and 1% significance. Estimation sample: 2022Q3–2025Q3.

Table A10
Composition of disclosed WMP holdings by bank group

Asset category	National banks	Local banks	All banks
Panel A. Mean quarterly reported value (RMB trillion)			
Standard LGFV bonds	0.15	0.27	0.43
Other standard bonds	0.91	0.47	1.39
Private credit	0.32	0.11	0.43
Other disclosed assets	5.34	1.41	6.75
Panel B. Portfolio-weight share (%)			
Standard LGFV bonds	5.4	16.4	11.6
Other standard bonds	16.3	23.4	20.3
Private credit	11.6	6.2	8.5
Other disclosed assets	66.7	54.0	59.6
Panel C. Holding-observation share (%)			
Standard LGFV bonds	8.6	25.6	16.6
Other standard bonds	31.4	37.3	34.2
Private credit	4.5	2.2	3.4
Other disclosed assets	55.4	34.9	45.8

Notes: Entries describe the composition of disclosed WMP holdings for products issued by national banks (state-owned and joint-stock commercial banks), local banks (all other banks), and all banks, pooled over 2022Q1–2025Q3. Each holding record is assigned to one asset category. Panel A reports the average quarterly disclosed value in RMB trillion, Panel B the share of disclosed portfolio weight, and Panel C the share of holding records, all within bank group. Portfolio weights are the position weights reported by products. Other disclosed assets include deposits, funds, trusts, and other investment vehicles.

Issuer province × quarter fixed effects	No	No	Yes	No	No
Issuer city × quarter fixed effects	No	No	No	Yes	Yes
Standard errors	Robust	Robust	Robust	Robust	Robust

Notes: We use equation (6) to compare same-city and other-city provincial purchase shares. Observations are issues in 2022Q1–2025Q3. Later issues lack holdings coverage and are excluded rather than assigned zero ownership. Yield concession is 100 times the difference between the CSI valuation spread and the coupon-based issue spread, both in percentage points, giving bp. A larger concession means a lower issue yield, hence a higher price relative to the valuation benchmark. Purchase shares are WMP holdings first disclosed in the issue quarter divided by the bond's total issued amount, in pp, used to proxy primary-market purchases. Same-city buyers are headquartered in the issuer's city, and other-city buyers are elsewhere in its province. Same-city purchase share is positive for 2.7% of LGFV issues, with a conditional mean of 9.8 pp. Columns 1–4 use LGFVs and column 5 other issuers. The common LGFV sample has 21,116 issues, and removing singletons leaves 20,526 in column 4. All nine controls are displayed, and dashes mean not included or absorbed. The contrast is $\beta_C - \beta_P$, the same-city minus the other-city coefficient. Parentheses and stars use heteroskedasticity-robust inference. Issuer clustering gives contrast SE 0.355 and $p = 0.0044$ in column 4. Stars denote 10%, 5%, and 1% significance. Estimation sample: 2022Q1–2025Q3.

Table A12
Local WMP purchase shares and subsequent issuer distress

Issuer city × quarter fixed effects	No	No	No	Yes	Yes
Standard errors	Robust	Robust	Robust	Robust	Robust

Notes: We use equation (6) to test whether favorable same-city pricing accompanies lower subsequent issuer distress, conditional on observed issue risk. Observations are bonds issued in 2022Q1–2023Q4 by previously undistressed issuers. The outcome equals 100 if the issuer records its first credit event within eight quarters, and zero otherwise. Events include defaults, rating warnings, and guarantor events, observed through 2025Q4, so every bond has a complete eight-quarter window. Purchase shares and controls follow Table A11, adding the public (CSI) valuation spread to control for ex ante risk. Columns 1–4 use LGFV bonds and column 5 other issuers. Parentheses contain heteroskedasticity-robust standard errors. Stars denote 10%, 5%, and 1% significance. Estimation sample: 2022Q1–2023Q4.

Observations	20,172	20,172	20,172
Month fixed effects	No	Yes	Yes
Reported rating fixed effects	No	No	Yes
Standard errors	Issuer	Issuer	Issuer

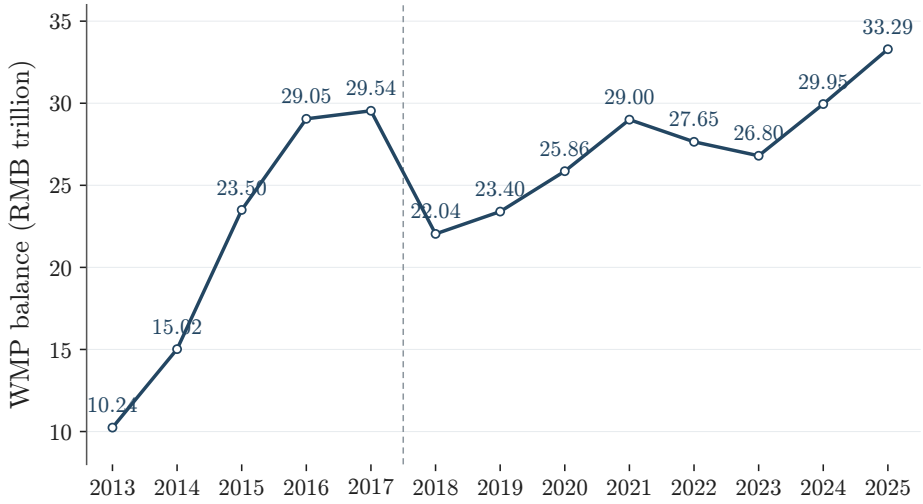

Notes: Panel A describes unique RMB fixed-rate bonds issued at par in 2022Q1–2023Q3. Panel B regresses issuance yields (pp) on issuer-type indicators, with other nonfinancial issuers omitted. All columns use the same sample, and later columns add the displayed issue characteristics, issue-month effects, and reported ratings (including a category for missing ratings). Unlike Table A3, Panel E, the sample does not require observed issuer assets. CDs, convertibles, exchangeables, structured, perpetual, subordinated, floating-rate, and reset-rate bonds are excluded. There is no winsorization. Parentheses contain issuer-clustered errors, and stars indicate 10%, 5%, and 1% significance. For these fixed-rate, at-par issues, the stated rate equals the contractual yield at issuance. Estimation sample: 2022Q1–2023Q3.

Figure A1
Chinese asset-management products and WMP asset allocation, 2025

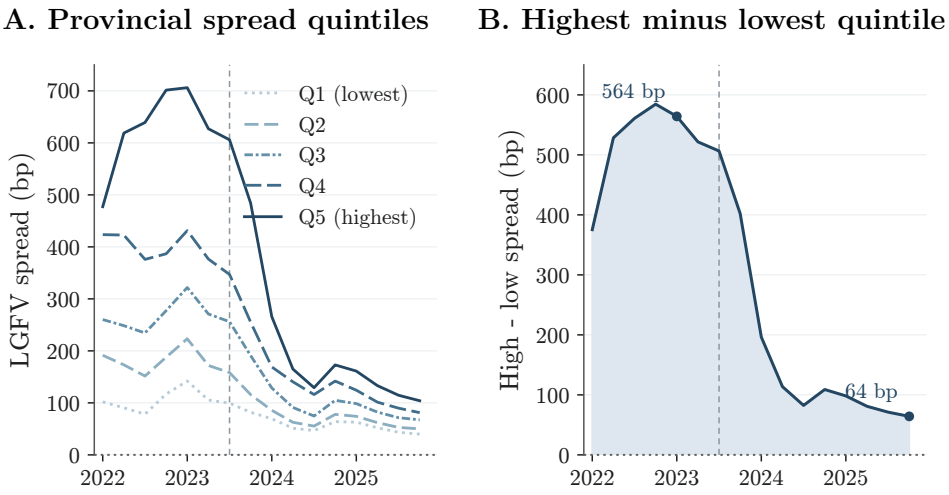

Notes: Panel A reports assets under management of Chinese asset-management products at the end of 2025, in RMB trillion, and Panel B reports the asset allocation of bank WMPs, in percent. Balances overlap through cross-investment. Private AM denotes private asset-management plans. Sources: Asset Management Association of China and annual WMP market reports.

Figure A2
Bank WMP balances, 2013–2025

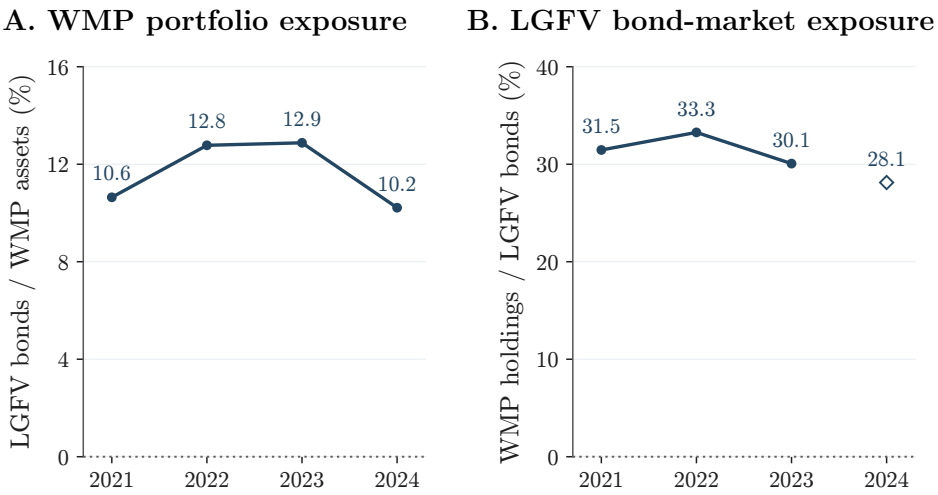

Notes: The figure plots outstanding bank WMP balances at year end, in RMB trillion. The dashed line marks a change in the statistical definition in 2018, when guaranteed and certain structured products were reclassified outside bank wealth management.

Figure A3
Provincial LGFV spreads by pre-announcement spread quintile

Notes: Provinces are grouped into quintiles of their mean LGFV spread over 2022Q1–2023Q2, before the July 2023 announcement. Panel A plots the mean spread of each quintile, and Panel B plots the difference between the highest and lowest quintiles. The highest-minus-lowest gap falls from 564.2 bp in 2023Q1 to 64.2 bp in 2025Q4. The dashed line marks 2023Q3.

Figure A4
The scale of the WMP–LGFV bond link, 2021–2024

Notes: Both panels use estimated holdings $\widehat{H}_t = B_t q_t$ from Internet Appendix D.8, which multiply industry WMP bond assets B_t by the LGFV share q_t of bonds in disclosed year-end holdings. Panel A divides by official WMP net assets under management, and Panel B divides by the published LGFV bond balance. The open diamond marks the change in the source of the LGFV bond balance in 2024. Sources: Wind disclosures, annual WMP market reports, Lianhe Ratings (2024), and Zhang (2025).

Internet Appendix B
Model Derivations and Numerical Solution

This appendix derives the results of the model in Section 6, and Internet Appendix C gives proofs. Subsection B.6 solves the full equilibrium numerically, without the first-order approximations used in the text.

B.1 Savers and market shares

Savers' risk aversion γ has a nondegenerate distribution G on $[\underline{\gamma}, \overline{\gamma}]$, where $0 < \underline{\gamma} < \overline{\gamma} < \infty$, with utility given by equation (16). Bounded support permits differentiation under the integral. Under the logit assumption on savers' tastes, the share of savers with risk aversion γ choosing bank b is equation (17). Holding rivals' portfolios fixed,

$$\frac{\partial s_b(\gamma)}{\partial x_b} = \beta s_b(\gamma)\big(1 - s_b(\gamma)\big)\big[\mu_B - \gamma\big(\sigma_B^2 x_b + \sigma_{B,PC} n_b\big)\big],$$
$$\frac{\partial s_b(\gamma)}{\partial n_b} = \beta s_b(\gamma)\big(1 - s_b(\gamma)\big)\big[\mu_{PC} - \gamma\big(\sigma_{B,PC} x_b + \sigma_{PC}^2 n_b\big)\big], \qquad \frac{\partial s_b(\gamma)}{\partial a_b} = \gamma\, s_b(\gamma)\big(1 - s_b(\gamma)\big). \tag{B.1}$$

The small-share approximation treats $s_b(\gamma)$ as small for every bank and saver type, so $s_b(\gamma)(1 - s_b(\gamma)) \approx s_b(\gamma)$. A bank's marginal savers then have approximately the same distribution as its savers, and the two distributions coincide in the small-share limit used for the analytic comparative statics. Subsection B.6 instead retains the full demand system, including a large national-bank share. For any two banks, and whatever their shares, equation (17) gives equation (26):

$$\log s_b(\gamma) - \log s_{b'}(\gamma) = \beta\big(R_b - R_{b'}\big) + \gamma\Big[\big(a_b - a_{b'}\big) - \frac{\beta}{2}\big(V_b - V_{b'}\big)\Big]. \tag{B.2}$$

B.2 Portfolio choice

Integrating equation (B.1) over G gives

$$\frac{\partial s_b}{\partial x_b} = \beta W_b\big[\mu_B - \bar{\gamma}_b\big(\sigma_B^2 x_b + \sigma_{B,PC} n_b\big)\big], \qquad \frac{\partial s_b}{\partial n_b} = \beta W_b\big[\mu_{PC} - \bar{\gamma}_b\big(\sigma_{B,PC} x_b + \sigma_{PC}^2 n_b\big)\big],$$

where $W_b = \int s_b(\gamma)(1 - s_b(\gamma))\, dG(\gamma) > 0$ and $\bar{\gamma}_b$ is defined in equation (20). The variance used in the sorting and scale conditions is $\mathrm{Var}_b(\gamma) = W_b^{-1} \int (\gamma - \bar{\gamma}_b)^2 s_b(\gamma)(1 - s_b(\gamma))\, dG(\gamma)$. Conditional on the investment regime, the fixed cost does not vary with the portfolio.

For completeness, let $z_b = (x_b, n_b)'$, $\mu = (\mu_B, \mu_{PC})'$, and let Σ be the covariance matrix of the two assets. At a constrained optimum with private credit access, the necessary conditions

are

$$\beta W_b(\mu - \bar{\gamma}_b \Sigma z_b) - \lambda_b \mathbf{1} + \nu_b = 0, \qquad \lambda_b(1 - \mathbf{1}' z_b) = 0, \qquad \nu_{bj} z_{bj} = 0,$$

with $z_b \geq 0$, $\mathbf{1}' z_b \leq 1$, $\lambda_b \geq 0$, and $\nu_b \geq 0$. Here $\mathbf{1} = (1, 1)'$, λ_b is the budget multiplier, and ν_{bj} enforces nonnegative investment in asset j. The bond-only problem restricts $n_b = 0$ and optimizes over $0 \leq x_b \leq 1$. The interior cases used in the text set the relevant multipliers to zero, giving equation (21). These conditions are necessary but not generally sufficient for an exact best response because market share need not be globally concave. The feasible sets are compact and share is continuous, so a maximizer exists within each regime, and Subsection B.6 checks the computed choices numerically.

Holding marginal savers fixed gives the quadratic objective $Q_b(z) = \mu' z - \bar{\gamma}_b z' \Sigma z / 2$. The maintained covariance restrictions imply $\det \Sigma = \sigma_B^2 \sigma_{PC}^2 - \sigma_{B,PC}^2 > 0$, so Q_b is strictly concave. Its constrained maximizer is unique, and its interior choices are equations (22) and (24). The bond-only value is $\mu_B^2 / (2\bar{\gamma}_b \sigma_B^2)$. To see the gain from private credit, write $\chi = \sigma_{B,PC} / \sigma_B^2$ and $\omega = \sigma_{PC}^2 - \sigma_{B,PC}^2 / \sigma_B^2 > 0$. After optimizing the bond position, the additional value is $(\mu_{PC} - \chi \mu_B) n - \bar{\gamma}_b \omega n^2 / 2$. Its interior maximum is g_b in equation (25). If $\mu_{PC} \leq \chi \mu_B$ and the bond-only optimum is interior, the optimal private credit position and its gain are zero. If a portfolio constraint binds, the constrained solution replaces the interior formulas.

In the full demand system, a portfolio changes which savers are marginal, so an interior candidate best response solves equation (21) as a fixed point. The two regimes generally have different values $\bar{\gamma}_b^B$ and $\bar{\gamma}_b^{PC}$. The cross-regime formula $x_b^{PC} = x_b^B - \chi n_b^{PC}$ and quadratic gain g_b apply with a common, fixed $\bar{\gamma}_b$. Exact entry instead compares maximized shares, allowing the weights to differ. Subsection B.6 computes each portfolio with the marginal savers it attracts.

B.3 Sorting by reputation

Proposition B.1 (Sorting). *In the small-share case, holding portfolios fixed,*

$$\frac{\partial \bar{\gamma}_b}{\partial a_b} = \mathrm{Var}_b(\gamma), \qquad \frac{\partial \log s_b}{\partial a_b} = \bar{\gamma}_b. \tag{B.3}$$

Along an interior bond-only optimum, holding rivals' offers fixed and allowing the bank's bond share to respond,

$$\frac{d\bar{\gamma}_b}{da_b} = \frac{\mathrm{Var}_b(\gamma)}{1 - \beta \sigma_B^2 \, (x_b^B)^2 \, \mathrm{Var}_b(\gamma) / \bar{\gamma}_b}, \qquad \frac{dx_b^B}{da_b} = -\frac{x_b^B}{\bar{\gamma}_b} \frac{d\bar{\gamma}_b}{da_b}, \tag{B.4}$$

with $d\bar{\gamma}_b / da_b > 0$ and $dx_b^B / da_b < 0$ when the denominator is positive. In the small-share case, if $a_b - a_{b'} > \beta \sigma_{PC}^2 / 2$, then $\bar{\gamma}_b > \bar{\gamma}_{b'}$ for any feasible portfolios, and if both banks have interior bond-only choices, $x_b^B < x_{b'}^B$.

The bond-only portfolio behind Prediction 1 is

$$x_b^B = \frac{\mu_B}{\bar{\gamma}_b \, \sigma_B^2}. \tag{B.5}$$

Using the fixed-portfolio sorting derivative in equation (B.3), its dependence on reputation through marginal-saver risk aversion is

$$\frac{\partial \log x_b^B}{\partial a_b} = -\frac{1}{\bar{\gamma}_b} \frac{\partial \bar{\gamma}_b}{\partial a_b} = -\frac{\mathrm{Var}_b(\gamma)}{\bar{\gamma}_b} < 0. \tag{B.6}$$

Equation (B.4) allows the portfolio itself to adjust and gives the corresponding total derivative under its stated condition. The portfolio response reinforces the sorting. A bank that holds fewer bonds offers a safer portfolio, which attracts still more cautious savers. Outside the small-share case, the ordering still holds for all of a bank's savers but need not hold for its marginal savers, whose weights $s_b(\gamma)(1 - s_b(\gamma))$ fall where a bank serves most of a group. The numerical equilibrium in Subsection B.6, in which the national bank has a large share, confirms the ordering of $\bar{\gamma}_b$ for its parameters. The condition in the last statement of Proposition B.1 ensures that the reputation gap outweighs any difference in portfolio risk, because no feasible portfolio has variance above σ_{PC}^2. In the data, FY2021 bank assets proxy for the reputation and distribution network that determine a bank's share.

B.4 Scale and entry into private credit

Access to private credit changes the risk-adjusted return offered to saver type γ by $\Delta v_b(\gamma) = \Delta R_b - \frac{\gamma}{2} \Delta V_b$, where in this subsection Δ compares the bank's exact optimal portfolios with and without access, not the two resolution states. This change need not be positive for every saver type. Holding rivals' portfolios fixed, the fee gain is

$$\Pi_b = f \int s_b(\gamma) \, \frac{(1 - s_b(\gamma)) \left(e^{\beta \Delta v_b(\gamma)} - 1 \right)}{1 - s_b(\gamma) + s_b(\gamma) e^{\beta \Delta v_b(\gamma)}} \, dG(\gamma), \tag{B.7}$$

where $s_b(\gamma)$ is its bond-only share before the portfolio change. Since access expands the feasible set, $\Pi_b \geq 0$. A first-time entrant pays the cost if and only if $\Pi_b \geq F$, taking entry at indifference. A bank that has arranged private credit before pays no further cost and holds it whenever access strictly improves its optimum. Equivalently, $\Pi_b = f(s_b^{PC} - s_b^B)$, the exact comparison in equation (28).

Proposition B.2 (Scale and entry)**.** *In the small-share case, the first-order approximation to the fee gain is* $\widetilde{\Pi}_b = f \beta s_b g_b$*, with* s_b *the bond-only market share and* g_b *in equation* (25)*. Along an interior bond-only optimum in a fixed competitive environment, allowing the bond*

share to respond to reputation,

$$\frac{d\log\widetilde{\Pi}_b}{da_b} = \bar{\gamma}_b - \frac{1}{\bar{\gamma}_b}\frac{d\bar{\gamma}_b}{da_b}, \tag{B.8}$$

which is positive whenever $\mathrm{Var}_b(\gamma)\,(1+\beta R_b) < \bar{\gamma}_b^2$*, where* $R_b = \mu_B x_b^B$ *is expected excess return. If this condition holds along the interior optimum for all reputations between* a_S *and* a_L*, then* $\widetilde{\Pi}_L > \widetilde{\Pi}_S$*. In this first-order entry benchmark, the large bank enters whenever the small bank does, and for* $\widetilde{\Pi}_S < F \le \widetilde{\Pi}_L$ *only the large bank enters.*

The condition bounds the dispersion of risk aversion among marginal savers relative to its mean. Holding portfolios fixed, it is $\mathrm{Var}_b(\gamma) < \bar{\gamma}_b^2$, and the factor $1 + \beta R_b$ accounts for the portfolio response in equation (B.4). Under this condition, the proportional increase in the investor base exceeds the proportional decline in the value of the substitute to marginal savers. The exact entry comparisons below use Π_b rather than $\widetilde{\Pi}_b$. Because the cost is paid by the WMP business rather than each product, launching a new product does not remove it.

B.5 Debt resolution, substitution, and market shares

Debt resolution lowers the bond's expected excess return from $\mu_{B,0}$ to $\mu_{B,1} = (1-\tau)\mu_{B,0}$, with $0 < \tau < 1$. Subscripts 0 and 1 denote values before and after resolution. The return and risk of private credit are unchanged. To allow resolution to make bonds safer as well, the bond variance may fall from $\sigma_{B,0}^2$ to $\sigma_{B,1}^2 \le \sigma_{B,0}^2$, retaining a positive-definite covariance matrix and interior conditional choices. The propositions hold the composition of each bank's marginal savers, $\bar{\gamma}_b$, fixed across the two states, and Subsection B.6 lets it adjust.

Proposition B.3 (Bond retreat)**.** *A bank without private credit changes its bond share by*

$$\Delta x_b = \left[(1-\tau)\frac{\sigma_{B,0}^2}{\sigma_{B,1}^2} - 1\right] x_{b,0}^B, \tag{B.9}$$

which is proportional to its initial bond share and negative if and only if

$$\frac{\mu_{B,1}}{\sigma_{B,1}^2} < \frac{\mu_{B,0}}{\sigma_{B,0}^2}. \tag{B.10}$$

With unchanged bond risk, $\Delta x_b = -\tau x_{b,0}^B$*. A bank that holds private credit before and after resolution, with unchanged risks, changes its bond share by* $-\tau\sigma_{PC}^2\mu_{B,0}/\left[\bar{\gamma}_b(\sigma_B^2\sigma_{PC}^2 - \sigma_{B,PC}^2)\right]$*, which is also proportional to the bond return it loses.*

With unchanged bond risk, the bond retreat can also be written in primitives:

$$\Delta x_b = -\tau\, x_{b,0}^B = -\tau\,\frac{\mu_{B,0}}{\bar{\gamma}_b\,\sigma_B^2}. \tag{B.11}$$

Equivalently, $\partial^2 \Delta x_b / (\partial \tau \, \partial x_{b,0}^B) = -1$, so a larger initial position produces a stronger response to resolution. This exposure interaction is examined in Section 4.4 and Table 5. This benchmark applies to banks that stay bond-only, holding marginal savers fixed. Condition (B.10) states that yield compression must outweigh any reduction in bond risk for banks to hold fewer bonds. The empirical reliance measure, Initial home overweight$_a$, includes other home credit and subtracts a nationwide benchmark, so it proxies initial exposure to the affected investment.

For the remaining results, hold bond risk fixed. Write $g_{b,0}$ and $g_{b,1}$ for the gain from private credit before and after resolution, and $\Pi_{b,0}$ and $\Pi_{b,1}$ for the corresponding fee gains in equation (B.7), evaluated at equilibrium portfolios.

Proposition B.4 (Entry after debt resolution)**.** *Suppose the exact pre-resolution fee gains satisfy $\Pi_{S,0} \leq \Pi_{L,0}$. The scale condition motivates this ordering, and Subsection B.6 verifies it directly. If $\mu_{PC} > (\sigma_{B,PC}/\sigma_B^2)\mu_{B,0}$, the gain from private credit rises with resolution,*

$$\frac{\partial g_b}{\partial \tau} = \frac{\sigma_{B,PC}}{\sigma_B^2} \, \mu_{B,0} \, n_b^{PC} > 0, \tag{B.12}$$

where n_b^{PC} is the conditional position in equation (24). At a given market share, the first-order fee gain $\widetilde{\Pi}_b = f\beta s_b g_b$ therefore rises. If the bond-only market share also changes, $d\widetilde{\Pi}_b/d\tau = f\beta\Big(s_b \, dg_b/d\tau + g_b \, ds_b/d\tau\Big)$. The exact fee gains support entry by the national bank before resolution, entry by the large local bank only afterward, and no entry by the small local bank whenever

$$\max\{\Pi_{L,0}, \, \Pi_{S,1}\} < F \leq \min\{\Pi_{L,1}, \, \Pi_{N,0}\}. \tag{B.13}$$

For an entrant, the combined share of bonds and private credit changes by

$$\Delta(x_b + n_b) = -\tau x_{b,0}^B + \frac{\sigma_B^2 - \sigma_{B,PC}}{\sigma_B^2} \, n_{b,1}, \tag{B.14}$$

which is positive when the new private credit position is large relative to the bond retreat.

The interval in condition (B.13) is nonempty when both upper bounds exceed its lower bound. This requires enough post-resolution fee income to make entry worthwhile for the large local bank, while the small bank's gain remains below the cost. Subsection B.6 verifies these comparisons with endogenous market shares rather than inferring them from the yield change alone.

The portfolio expression behind Prediction 2 combines the first-order entry benchmark with the private credit choice at fixed marginal savers. After resolution,

$$\begin{aligned} n_{b,1}^* &= \mathbb{1}\{\widetilde{\Pi}_{b,1} \geq F \text{ or } e_b = 0\} \, n_{b,1}^{PC}, \\ n_{b,1}^{PC} &= \frac{\mu_{PC} - (\sigma_{B,PC}/\sigma_B^2)(1-\tau)\mu_{B,0}}{\bar{\gamma}_b\Big(\sigma_{PC}^2 - \sigma_{B,PC}^2/\sigma_B^2\Big)}. \end{aligned} \tag{B.15}$$

Here $\widetilde{\Pi}_{b,1} = f\beta s^B_{b,1} g_{b,1}$, with $s^B_{b,1}$ the post-resolution bond-only market share, and e_b records whether the bank has already paid the fixed cost. The exact problem instead compares maximized shares using equation (28) and computes each portfolio with its own marginal savers. Substituting $g_{b,1}$ into the first-order entry benchmark gives, for a first-time entrant,

$$\frac{s_b}{\bar{\gamma}_b} \geq \frac{2F\left(\sigma^2_{PC} - \sigma^2_{B,PC}/\sigma^2_B\right)}{f\beta\left(\mu_{PC} - (\sigma_{B,PC}/\sigma^2_B)(1-\tau)\mu_{B,0}\right)^2}. \tag{B.16}$$

In this approximation, s_b is the bank's bond-only share at the date of the comparison. Holding the portfolio fixed, equation (B.3) gives $\partial \log(s_b/\bar{\gamma}_b)/\partial a_b = \bar{\gamma}_b - \mathrm{Var}_b(\gamma)/\bar{\gamma}_b$, positive when $\mathrm{Var}_b(\gamma) < \bar{\gamma}^2_b$. Proposition B.2 gives the stronger condition when that portfolio adjusts. Holding market shares and marginal savers fixed as resolution intensifies, the right side of equation (B.16) falls: a lower bond return makes private credit more valuable and lowers the entry cutoff. The full numerical solution lets both market shares and marginal savers change.

For a bank that already used private credit, $e_b = 0$ and the entry condition is no longer binding. Subtracting its pre-resolution conditional position from equation (B.15), with risks and marginal-saver composition fixed and both portfolios interior, gives

$$\Delta n^{PC}_b = \frac{\tau\, \sigma_{B,PC}\, \mu_{B,0}}{\bar{\gamma}_b\left(\sigma^2_B \sigma^2_{PC} - \sigma^2_{B,PC}\right)} > 0. \tag{B.17}$$

Positive covariance makes bonds and private credit substitutes in the portfolio. A lower bond yield raises the optimal private credit position without a second payment of the fixed cost. The model thus separates expansion by existing users from scale-dependent first entry. The observed increase in private credit can contain both, and a newly launched WMP is not itself a first entry by its bank.

Proposition B.5 (Returns and market shares)**.** *Suppose $\bar{\gamma}_L > \bar{\gamma}_S$, as under the sorting condition, neither local bank holds private credit before resolution, and only the large bank enters afterward. Holding marginal savers fixed and under the interior-portfolio conditions, the entrant's expected return changes relative to the small bank by*

$$\Delta R_L - \Delta R_S = \tau(2-\tau)\,\mu_{B,0}\left(x^B_{S,0} - x^B_{L,0}\right) + \left(\mu_{PC} - \frac{\sigma_{B,PC}}{\sigma^2_B}\mu_{B,1}\right) n_{L,1} > 0, \tag{B.18}$$

and, in the small-share case, to first order in utility changes and holding the national bank's offer fixed, its market share grows faster:

$$\Delta \log s_L - \Delta \log s_S \simeq \beta\left[\frac{\tau(2-\tau)}{2}\,\mu_{B,0}\left(x^B_{S,0} - x^B_{L,0}\right) + g_{L,1}\right] > 0. \tag{B.19}$$

Both terms are positive. The small bank held more bonds (Proposition B.1), so it loses more bond income, and only the large bank gains from private credit.

The individual-bank decomposition behind Prediction 3 makes these two channels explicit. For either local bank b, which holds no private credit before resolution, holding marginal savers fixed,

$$\begin{aligned}\Delta R_b = & -\tau(2-\tau)\,\mu_{B,0}\,x^B_{b,0} \\ & + \mathbb{1}\{b \text{ enters}\}\Big(\mu_{PC} - \frac{\sigma_{B,PC}}{\sigma_B^2}\mu_{B,1}\Big)n^{PC}_{b,1}.\end{aligned} \tag{B.20}$$

The first term is lost bond income, and the second is income from private credit, which only the entrant earns. For the two local banks, in the small-share approximation, to first order and holding the national bank's offer fixed,

$$\begin{aligned}\Delta\log s_b - \Delta\log s_{b'} &\simeq \beta\Big(\Delta v_b - \Delta v_{b'}\Big), \\ \Delta v_b &= -\frac{\tau(2-\tau)}{2}\,\mu_{B,0}\,x^B_{b,0} + \mathbb{1}\{b \text{ enters}\}\,g_{b,1}.\end{aligned} \tag{B.21}$$

Here Δv_b is the change in risk-adjusted return evaluated at the bank's fixed marginal-saver risk aversion, and $g_{b,1}$ is the post-resolution gain from private credit. Finally, substituting equation (B.5) into the relative-return comparison gives

$$\begin{aligned}\Delta R_L - \Delta R_S = \tau(2-\tau)\,\frac{\mu^2_{B,0}}{\sigma_B^2}\Big(\frac{1}{\bar\gamma_S} - \frac{1}{\bar\gamma_L}\Big) \\ + \Big(\mu_{PC} - \frac{\sigma_{B,PC}}{\sigma_B^2}\mu_{B,1}\Big)n^{PC}_{L,1} > 0.\end{aligned} \tag{B.22}$$

The first term is positive under the sorting condition, and the second is positive when only the large local bank enters. At that bank, the conditional share $n^{PC}_{L,1}$ equals its actual private credit share $n_{L,1}$ in Proposition B.5. The national bank, which already holds private credit before resolution, is not part of this entrant–nonentrant comparison.

B.6 Numerical solution of the full equilibrium

The propositions use the small-share case, first-order approximations, and a fixed composition of marginal savers. We now compute a three-bank equilibrium of the full demand system for an illustrative parameterization. Savers' risk aversion is lognormal with log mean 1.0 and log standard deviation 0.6, truncated to $[0.4, 15]$. We set $\beta = 60$, $f = 1$, $\mu_B = 0.012$, $\mu_{PC} = 0.022$, $\sigma_B^2 = 0.012$, $\sigma_{PC}^2 = 0.040$, and $\sigma_{B,PC} = 0.008$. Reputations are $a_N = 0$, $a_L = -0.75$, and $a_S = -1.25$, and resolution lowers the bond return by $\tau = 0.5$. Each bank's portfolio is a numerically computed best response to its rivals' portfolios, with market shares obtained by

integrating equation (17) over the distribution of risk aversion. The fixed cost $F = 0.0077$ lies in the interval of condition (B.13).

Table B1
Full equilibrium of the model

	Before resolution			After resolution		
	National	Large local	Small local	National	Large local	Small local
Bond share x_b	0.226	0.509	0.629	0.047	0.079	0.307
Private credit share n_b	0.125	0	0	0.160	0.266	0
Market share s_b	0.483	0.073	0.031	0.472	0.077	0.027
Marginal savers' risk aversion $\bar{\gamma}_b$	3.24	1.96	1.59	3.24	1.95	1.63
Expected excess return R_b (bp)	54.6	61.1	75.5	38.1	63.2	18.4
Fee gain from private credit Π_b	0.0130	0.0058	0.0032	0.0213	0.0090	0.0048

Notes: Numerically computed Nash equilibrium of the model in Section 6 with the illustrative parameters in the text. The fee gain compares optimized portfolios with and without private credit access, holding rivals' portfolios fixed. The fixed cost is 0.0077. Before resolution, only the national bank's gain exceeds the cost. Afterward, the large local bank's gain does as well, the small bank's does not, and the national bank keeps access without paying again. In the counterfactual equilibrium restricting all three banks to bonds, their pre-resolution bond shares are 0.308, 0.510, and 0.629.

All three predictions hold in this numerical example (Table B1). Bond shares fall with reputation, and the more reputable banks' marginal savers are more risk averse. In the counterfactual with all three banks restricted to bonds, resolution lowers their bond shares by 0.154, 0.259, and 0.321, close to $\tau x_b^B = 0.154$, 0.255, and 0.315. The exact fee gain from private credit is larger at more reputable banks and rises after resolution, and only the large local bank newly crosses the fixed cost. The large bank's expected return rises by 59 basis points relative to the small bank's, and the log of its market share relative to the small bank's rises by 0.17. Before resolution, the scale-condition ratio $\mathrm{Var}_b(\gamma)(1+\beta R_b)/\bar{\gamma}_b^2$ is 0.31 at the large local bank and 0.29 at the small one. Both ratios are below one, consistent with the scale condition, and the exact fee comparisons establish the entry pattern for this example.

We check each bank before and after resolution, with and without private credit access. Holding rivals' equilibrium portfolios fixed, a search of the feasible set $\{x_b, n_b \geq 0,\ x_b + n_b \leq 1\}$ in steps of 0.002 finds no higher market share. Constrained optimizations from six starting portfolios agree within 10^{-7}. The solutions are feasible, have first-order residuals below 10^{-7}, and have negative-definite Hessians within each regime. Increasing integration accuracy from 400 to 800 Gauss–Legendre nodes leaves every reported table entry unchanged. These checks support the computed best responses but do not prove uniqueness or global optimality. The post-resolution large local bank's marginal risk aversion is 1.996 in the bond-only optimum and 1.953 with private credit, illustrating why the exact comparison allows the weights to differ.

Internet Appendix C
Proofs

C.1. Proof of Proposition B.1

In the small-share case, $s_b(\gamma) = \exp(u_b(\gamma))/D(\gamma)$, with $u_b(\gamma) = \gamma a_b + \beta(R_b - \gamma V_b/2)$ and $D(\gamma)$ the denominator in equation (17), whose dependence on bank b's own offer is negligible. The weights defining $\bar{\gamma}_b$ are then proportional to $\exp(\gamma t_b)\, h_b(\gamma)$, where $t_b = a_b - \beta V_b/2$ and $h_b(\gamma) = e^{\beta R_b}\, dG(\gamma)/D(\gamma)$ does not depend on a_b. This is an exponential tilting of a fixed distribution, so the derivative of its mean with respect to the tilt t_b is its variance, which gives $\partial\bar{\gamma}_b/\partial a_b = \mathrm{Var}_b(\gamma)$ holding the portfolio fixed. Similarly, $\partial \log s_b/\partial a_b = \int \gamma\, s_b(\gamma)\, dG / \int s_b(\gamma)\, dG = \bar{\gamma}_b$.

For a bank without private credit, $V_b = \sigma_B^2 (x_b^B)^2$ and $x_b^B = \mu_B/(\bar{\gamma}_b \sigma_B^2)$. Then $d\bar{\gamma}_b/da_b = \mathrm{Var}_b(\gamma)\, dt_b/da_b$, with $dt_b/da_b = 1 - \beta\sigma_B^2 x_b^B\, dx_b^B/da_b$ and $dx_b^B/da_b = -(x_b^B/\bar{\gamma}_b)\, d\bar{\gamma}_b/da_b$. Substituting the last expression into the first and solving gives equation (B.4).

For the final statement, equation (B.2) shows that $s_b(\gamma)/s_{b'}(\gamma)$ increases with γ when $(a_b - a_{b'}) - \frac{\beta}{2}(V_b - V_{b'}) > 0$. Every feasible portfolio has $0 \le V \le (x\sigma_B + n\sigma_{PC})^2 \le \sigma_{PC}^2$, so $a_b - a_{b'} > \beta\sigma_{PC}^2/2$ guarantees the inequality whatever the portfolios. The distribution of bank b's savers then dominates that of bank b''s savers in the likelihood-ratio order. In the small-share case, a bank's marginal savers have the same distribution as its savers, so $\bar{\gamma}_b > \bar{\gamma}_{b'}$. If neither bank holds private credit, equation (22) gives $x_b^B < x_{b'}^B$. □

C.2. Proof of Proposition B.2

In the small-share case, the integrand in equation (B.7) is approximately $s_b(\gamma)\big(e^{\beta\Delta v_b(\gamma)} - 1\big)$. Linearizing in $\beta\Delta v_b$ gives $f\beta \int s_b(\gamma)\Delta v_b(\gamma)\, dG = f\beta s_b\big(\Delta R_b - \frac{\bar{\gamma}_b}{2}\Delta V_b\big)$, with the weights evaluated at the bond-only optimum. Maximizing this linearized demand gain is equivalent to maximizing Q_b at fixed $\bar{\gamma}_b$. Under the interior conditions, the improvement is g_b in equation (25), so the optimized first-order gain is $\widetilde{\Pi}_b = f\beta s_b g_b$.

For the derivative, the bank's bond share maximizes s_b, so by the envelope theorem $d\log s_b/da_b = \partial \log s_b/\partial a_b = \bar{\gamma}_b$ in the small-share case. Since g_b is proportional to $1/\bar{\gamma}_b$, $d\log g_b/da_b = -(1/\bar{\gamma}_b)\, d\bar{\gamma}_b/da_b$, giving equation (B.8). Equation (B.4) gives $d\bar{\gamma}_b/da_b = \mathrm{Var}_b(\gamma)/(1 - k_b)$, where $k_b = \beta R_b \mathrm{Var}_b(\gamma)/\bar{\gamma}_b^2$. The condition $\mathrm{Var}_b(\gamma)(1 + \beta R_b) < \bar{\gamma}_b^2$ implies $k_b < 1$ and is equivalent to $\bar{\gamma}_b^2(1 - k_b) > \mathrm{Var}_b(\gamma)$, so the derivative is positive. Integrating along an interior optimum under the stated condition gives $\widetilde{\Pi}_L > \widetilde{\Pi}_S$. Comparing these first-order gains with F establishes the entry ordering in the approximation. Exact entry requires the optimized-share comparison in equation (B.7). □

C.3. Proof of Proposition B.3

By equation (22) with $\bar{\gamma}_b$ fixed, $x^B_{b,1} = (1-\tau)\mu_{B,0}/(\bar{\gamma}_b\sigma^2_{B,1}) = (1-\tau)(\sigma^2_{B,0}/\sigma^2_{B,1})\,x^B_{b,0}$, which gives equation (B.9). The bracket is negative if and only if $(1-\tau)/\sigma^2_{B,1} < 1/\sigma^2_{B,0}$, which is condition (B.10). For a bank that holds private credit in both states, solving equation (21) gives $x_b = (\sigma^2_{PC}\mu_B - \sigma_{B,PC}\mu_{PC})/[\bar{\gamma}_b(\sigma^2_B\sigma^2_{PC} - \sigma^2_{B,PC})]$. With unchanged risks and μ_{PC}, the change is $-\tau\sigma^2_{PC}\mu_{B,0}/[\bar{\gamma}_b(\sigma^2_B\sigma^2_{PC} - \sigma^2_{B,PC})]$. □

C.4. Proof of Proposition B.4

With $\mu_B = (1-\tau)\mu_{B,0}$ in equation (25),

$$\frac{\partial g_b}{\partial \tau} = \frac{\big(\mu_{PC} - (\sigma_{B,PC}/\sigma^2_B)\mu_B\big)(\sigma_{B,PC}/\sigma^2_B)\mu_{B,0}}{\bar{\gamma}_b\big(\sigma^2_{PC} - \sigma^2_{B,PC}/\sigma^2_B\big)} = \frac{\sigma_{B,PC}}{\sigma^2_B}\,\mu_{B,0}\,n^{PC}_b,$$

using equation (24). It is positive because $\mu_{PC} - (\sigma_{B,PC}/\sigma^2_B)\mu_B \geq \mu_{PC} - (\sigma_{B,PC}/\sigma^2_B)\mu_{B,0} > 0$. Equivalently, by the envelope theorem, a change in μ_B changes the best risk-adjusted return by the bonds held, x^{PC}_b with private credit and x^B_b without it, so $\partial g_b/\partial\mu_B = x^{PC}_b - x^B_b = -(\sigma_{B,PC}/\sigma^2_B)n^{PC}_b$. Because the first-order fee gain $f\beta s_b g_b$ increases with g_b, it is larger after resolution at any given share and composition of marginal savers.

For the entry pattern, every F in the interval (B.13) satisfies $\Pi_{N,0} \geq F$, $\Pi_{L,0} < F \leq \Pi_{L,1}$, and $\Pi_{S,1} < F$. The maintained pre-resolution ordering $\Pi_{S,0} \leq \Pi_{L,0}$ also implies $\Pi_{S,0} < F$. Thus only the national bank enters before resolution. Afterward, the large local bank enters and the small bank remains out. All gains are evaluated against rivals' portfolios in the corresponding regime. The interval is nonempty precisely when $\max\{\Pi_{L,0}, \Pi_{S,1}\} < \min\{\Pi_{L,1}, \Pi_{N,0}\}$.

For an entrant, equation (24) gives $x_{b,1} = (1-\tau)x^B_{b,0} - (\sigma_{B,PC}/\sigma^2_B)n_{b,1}$, so $\Delta(x_b + n_b) = -\tau x^B_{b,0} + (1 - \sigma_{B,PC}/\sigma^2_B)n_{b,1}$, which is equation (B.14). □

C.5. Proof of Proposition B.5

Write $\chi = \sigma_{B,PC}/\sigma^2_B$ for the bonds displaced per unit of private credit. A bank without private credit earns $R_b = \mu_B x^B_b = \mu^2_B/(\bar{\gamma}_b\sigma^2_B)$, so its expected return changes by $\big((1-\tau)^2 - 1\big)\mu_{B,0}x^B_{b,0} = -\tau(2-\tau)\mu_{B,0}x^B_{b,0}$. After resolution, the entrant holds $x^B_{L,1} - \chi n_{L,1}$ in bonds and $n_{L,1}$ in private credit, so its expected return is $\mu_{B,1}x^B_{L,1} + (\mu_{PC} - \chi\mu_{B,1})n_{L,1}$, and its change is $-\tau(2-\tau)\mu_{B,0}x^B_{L,0} + (\mu_{PC} - \chi\mu_{B,1})n_{L,1}$. Subtracting the small bank's change gives equation (B.18). The second term is positive because the entrant holds private credit only when $\mu_{PC} > \chi\mu_{B,1}$, and the first is positive because $x^B_{S,0} > x^B_{L,0}$ by Proposition B.1.

In the small-share case, $\log s_b(\gamma) = u_b(\gamma) - \log D(\gamma)$. Holding the national bank's offer fixed, $D(\gamma)$ does not change to first order, because the local banks' own shares are small. A

change in the bank's portfolio then changes $\log s_b$ by β times the change in the risk-adjusted return to its savers, evaluated at their average risk aversion $\bar{\gamma}_b$. The bond-only risk-adjusted return at $\bar{\gamma}_b$ is $\mu_B x_b^B/2$, which changes by $-\tau(2-\tau)\mu_{B,0}x_{b,0}^B/2$, and the entrant gains $g_{L,1}$ in addition. Subtracting gives equation (B.19). □

Internet Appendix D
Specifications and Supplementary Evidence

This appendix supplies the measurement and specification details behind the argument. Subsection D.1 identifies the borrowers that receive private credit, and Subsection D.2 details the spread and financing-rate comparisons. Subsections D.3–D.7 give the designs behind the redemption, bond-retreat, flow, return, and pricing tests. Subsection D.8 reconciles market-wide exposure with shares of included debt holdings. Subsection D.9 and Tables D1, D2, and D3 separate initial specialization from subsequent substitution. Tables D4–D5 assess the financing-rate comparison, and Figure D1 explains its 2023Q1 movement in rate levels. Return and business-balance checks are in Internet Appendix E.

D.1. Private-credit borrowers and the LGFV sector

To identify who receives private credit financing, we extract borrower names from asset descriptions, locate them using company registration records, and match them to LGFV bond issuers over 2022Q1–2025Q3. These matches account for about 60% of local banks' home private credit value before the program and 59% afterward. Adding a screen for borrower names with terms typical of local financing platforms raises the shares to 79% and 86%. For the largest FY2021 size tercile, the corresponding shares with the keyword screen are 77% and 85%. Most of this substitution therefore remains within the LGFV sector, although sector-level matches do not trace each bond into a contract with the same legal borrower.

D.2. Spread compression and financing-rate comparisons

The descriptive issuance averages in Section 4 compare 7,128 pre-implementation LGFV issues in 2022Q1–2023Q3 with 9,763 post-implementation issues in 2023Q4–2025Q4, without conditioning on WMP ownership. Each issue receives equal weight. This sample differs from the issuer-type comparison in Table A14. We retain fixed-rate, at-par, nonstructured, nonconvertible, nonperpetual, nonsubordinated bonds, so the reported issue rate measures yield at issuance. Each issue's spread subtracts the Treasury-curve yield on its issue date at the nearest available maturity node. The before period includes the announcement quarter, consistent with implementation beginning in 2023Q4.

To trace the timing of compression, we interact final refinancing intensity with quarter indicators. For province p in quarter q, the event-study specification is

$$\begin{aligned}\text{Bond spread}_{pq} = \alpha_p + \alpha_q \\ + \sum_{k \neq q_0} \beta_k \,\text{Final refinancing}_p^{GDP} \mathbb{1}\{q = k\} + \varepsilon_{pq}, \quad q_0 = 2023\text{Q2}.\end{aligned} \tag{D.1}$$

Bond spread$_{pq}$ is the province's secondary-market LGFV bond spread in basis points. Final intensity Final refinancing$_p^{GDP}$ is cumulative special-refinancing bond issuance at the last observed date, as a percentage of 2020 provincial GDP, and it is fixed across quarters. Province and quarter effects remove persistent provincial differences and common movements. The plotted β_k measures additional spread change since 2023Q2 per percentage point of final intensity (Figure 1). The sample is 2022Q1–2026Q1, and errors cluster by province. Spreads and intensity are winsorized at the 1st and 99th percentiles, and province effects absorb the intensity level.

Pre-announcement estimates are imprecise around zero. A province with one percentage point higher final intensity experiences 6.5 basis points more compression by 2023Q4 and 18.6 by 2025Q4. The difference deepens through 2024, indicating a persistent loss of additional yield where refinancing is greater.

The regression in Table A4 uses cumulative refinancing-bond issuance at each date rather than a fixed final exposure:

$$\begin{aligned}\text{Bond spread}_{pq} = \beta\, \text{Refinancing}_{pq}^{GDP} + \alpha_p + \alpha_q \\ + \text{Trend controls}_{pq} + \varepsilon_{pq}.\end{aligned} \tag{D.2}$$

Here the outcome is the province-quarter LGFV bond spread in basis points over 2022Q1–2025Q4, and intensity is cumulative refinancing as a percentage of 2020 provincial GDP. The effects α_p and α_q compare changes within provinces after removing common quarterly movements. Without trend controls, the coefficient is -17.67 basis points per percentage point of refinancing/GDP. The term Trend controls$_{pq}$ adds either the province's mean spread over 2022Q1–2023Q3 interacted with a linear trend or province-specific linear trends, as reported in each column. These additions distinguish the refinancing association from convergence related to initial spreads and from existing provincial trends. Both reduce its magnitude, to -2.43 and -8.65, but retain a negative association. Table A4 thus relates compression to refinancing, while Figure A3 shows the decline in the gap between provinces with high and low pre-announcement spreads.

To assess the income available from a substitute, we compare private credit yields with bond issuance yields for the same reporting issuer, the firm whose disclosures list the financing. Both are annual contractual rates on new financing. For bonds, the source records the stated issue rate. Table 4, Panel A, estimates

$$\begin{aligned}\text{Yield}_{jfq} = \alpha_{fq} + \alpha_{f,d(j)} + \alpha_{\text{mat}(j)} \\ + \sum_{t\neq 2022} \delta_t\, \mathbb{1}\{\text{Private credit}\}_j \mathbb{1}\{\text{Issue year}_j = t\} + e_{jfq}.\end{aligned} \tag{D.3}$$

Here j is a contract or bond issue, f its reporting issuer, and q its origination quarter. The outcome Yield$_{jfq}$ is the annual contractual rate in percentage points. The functions $d(j)$ and

mat(j) identify its debt type and maturity bin. The effects α_{fq} compare financing within an issuer and quarter, and $\alpha_{f,d(j)}$ absorb persistent differences between that issuer's financing channels. The year indicator uses the record's origination year, with t indexing calendar years. Thus δ_t measures the change in the private credit-minus-bond gap from 2022. The gap widens by 1.30 percentage points in 2024. This reporting-issuer sample can include financing by an issuer's affiliates, unlike the same-borrower event study.

The separate-channel columns in Panel A instead regress each record's rate on origination-year indicators, with 2022 omitted. The private credit regression absorbs borrower-by-creditor and maturity-bin effects, and the bond regression absorbs issuer-by-bond-type-by-placement and maturity-bin effects. Their year coefficients therefore compare rates within the relevant financing relationships or issue types. Both cluster errors by reporting issuer. Because each channel regression uses its own sample, the two year coefficients need not add to the gap, which the gap regression estimates directly.

The quarterly comparison in Figure 3 instead holds the legal borrower fixed. It requires the funded borrower's entity identifier (DM code) to equal the reporting issuer's code and matches bonds on that same code. Its initial pool contains borrower-quarters with both channels and borrowers with at least two matched quarters. We then require observed continuous maturity, restrict financing to 2021 onward, and remove borrower-month singletons. The resulting sample contains 17,303 financing records at 589 borrowers in 26 provinces. Contracts are dated by origination rather than disclosure. Repeated contracts and repeated records of the same bond issue are deduplicated, without further rate winsorization or outcome-based trimming. Because these restrictions can remove one channel, not every retained month or quarter still contains both. Mixed-channel months identify the direct rate gap, while other multi-observation months also inform the maturity slopes.

Equation (7) compares annual rates within borrower-by-calendar-month cells, controlling for continuous maturity with a separate slope in each quarter. It does not include borrower-by-debt-type effects. Quarterly coefficients estimate gap levels, and the plotted changes subtract the 2023Q2 gap using the full covariance matrix. In Table D4, we test whether the widening depends on maturity adjustment, financing frequency, or borrower composition. Column 2 allows separate maturity slopes by debt type and quarter and evaluates the gap at a common three-year maturity. Column 3 gives each borrower-quarter-debt-type cell total weight one, using inverse-frequency weights on the baseline sample. Column 4 retains the 101 borrowers with both channels in 2023Q2 and at least one later quarter after the baseline restrictions, without requiring a balanced panel. All four comparisons show a wider gap in 2024Q4 and 2025Q3.

The pre-program dip in 2023Q1 could reflect lower private credit yields or higher bond issuance yields. To separate the two, Figure D1 plots both rates for the same 22 legal borrowers, each receiving equal weight in every quarter from 2022Q4 through 2023Q3. Each borrower has both channels in at least one common month of every quarter. Bond issuance

yields rise from 4.25% in 2022Q4 to 4.78% in 2023Q1, then fall to 4.49% in Q2. Private credit rates instead move from 6.27% to 6.32% and 6.40%. The Q1 narrowing therefore reflects higher bond issuance yields rather than a collapse in private credit yields. A broader fixed set of 76 borrowers observed in both Q1 and Q2 gives the same direction: bond issuance yields fall 47 basis points while private credit rates rise 4. These descriptive comparisons fix borrowers and apply identical weights to the two channels, but contracts and maturities can change. The conditional regression separately adjusts for maturity.

In Table D5, we test whether the late-period widening depends on how we treat repeated financing records and regional dependence. The baseline uses one-way province clustering, allowing arbitrary dependence across borrowers and months within a province. Figure intervals are $\hat{\delta}_q \pm t_{25,.975}\, SE(\hat{\delta}_q)$, with 26 province clusters. We also use a null-imposed province wild bootstrap with 9,999 Webb-weight draws, whose confidence sets invert bootstrap-t tests. Dropping one province at a time, all 26 estimates remain positive for each reported quarter. Panel A reports the main late-period contrasts and their province-bootstrap confidence sets.

The second regression column of Table D5 gives each borrower-month with both channels one observation. For legal borrower f in calendar month m, let Yield gap$_{fm}$ be its mean PC yield minus mean bond issuance yield and Maturity gap$_{fm}$ its mean PC maturity minus mean bond maturity. As in the main event study, $q(m)$ identifies the quarter containing month m. We estimate

$$\begin{aligned}\text{Yield gap}_{fm} = &\sum_q b_q \mathbb{1}\{q(m) = q\} \\ &+ \sum_q \eta_q \,\text{Maturity gap}_{fm} \mathbb{1}\{q(m) = q\} + u_{fm}.\end{aligned} \tag{D.4}$$

We report $b_q - b_{2023Q2}$. Each channel mean weights contracts or bond issues equally. Differencing removes the common borrower-month condition, so no borrower effect is added. This regression uses 2,525 borrower-months at 557 borrowers in 25 provinces. It tests whether the wider gap remains when each such month contributes one observation rather than several financing records. The weighting and maturity adjustment differ from the contract-level regression. Province-clustered errors and 9,999 Webb-weight province draws support widening in both reported quarters. Panel B reports the underlying financing records, borrowers, and provinces by quarter. No usable 2025Q4 comparison survives the monthly design.

The priority-province comparison in Table 4, Panel B, uses the same issuer-years for each channel and the difference between them:

$$\begin{aligned}\text{Rate}^d_{ft} = \alpha^d_f + \alpha^d_t + \beta_d \mathbb{1}\{\text{Priority province}\}_{p_f} \mathbb{1}\{t = 2024\} \\ + \psi_d \mathbb{1}\{\text{Priority province}\}_{p_f} \mathbb{1}\{t = 2023\} + u^d_{ft}.\end{aligned} \tag{D.5}$$

The index f again denotes a reporting issuer and t a calendar year. Superscript $d \in \{PC, B, PC - B\}$ labels the outcome, which is the private credit yield, the bond issuance

yield, or their difference, and does not index time. The province p_f belongs to that issuer, not the WMP bank. The priority group comprises Tianjin, Inner Mongolia, Liaoning, Jilin, Heilongjiang, Guangxi, Chongqing, Guizhou, Yunnan, Gansu, Qinghai, and Ningxia. Issuer and year effects enter separately for each outcome, and the 2023 interaction allows a transition-year contrast. The coefficient β_d is the additional 2024 change in priority provinces, relative to their 2019–2022 level and to the same change in other provinces. Amount-weighted component rates are winsorized before subtraction, so their changes add to the gap on this common sample. Relative to other provinces, the 2024 gap widens by 1.04 percentage points: bond issuance yields fall an additional 0.73 points while the private credit rate change is positive but imprecise. The provincial comparison reinforces the distinction between compression in marketable bonds and the yield remaining on private credit.

D.3. Redemption terms and local holdings

We test whether local banks place more home investments in products whose withdrawal terms allow less liquid holdings (Table A6, equation (3)). The dependent variable is Portfolio home overweight$^{n}_{iq}$, defined in equation (D.12) of Subsection D.9: the share of the product's included debt holdings invested in home class n, minus the corresponding province's share of nationwide included holdings. The all-credit column sums this overweight across classes, giving Portfolio home overweight$_{iq}$. Controls are those listed for equation (3) in the main text. Quarter effects remove common movements. The local-bank coefficient compares daily-open products, and its interaction with restricted redemption measures how much wider the local–national allocation gap is in that segment. Together with local banks' 80.2% asset share in restricted-redemption products (Table A5), the estimates link their product design to their home investment strategy.

D.4. Home-bond allocation and refinancing pressure

We use equation (10) to test whether banks reduce home bond investment more than other buyers facing the same local bond supply (Table 6).

In this panel, a indexes the buying WMP-issuing institution (a bank or subsidiary), c the issuer city, and q the calendar quarter. Home identifies a local institution investing in a city of its underlying bank's home province, and Post begins in 2023Q4. The effects μ_{ac}, μ_{aq}, and μ_{cq} hold persistent buyer–city ties, buyer-wide conditions, and issuer-city conditions fixed. The baseline outcome is LGFV bond holdings in the city as a percentage of the buyer's current bond holdings. Other columns measure net holdings changes relative to current bond holdings and log one plus new purchases in RMB million. The Home–Post coefficient therefore compares changes by home and outside buyers of the same city's bonds. The estimated 0.45-point decline is about 12% of the initial mean allocation to cities in the bank's

home province. Replacing Home with separate own-city and rest-of-home-province indicators gives declines of 1.94 and 0.24 percentage points, respectively. Net holdings changes and new purchases also fall. Adding the interaction of Home buyer, Post, and the city's pre-program LGFV spread in percentage points to the new-purchase regression gives a larger purchase reduction in formerly higher-spread cities.

The related event study in Figure 4 aggregates issuer cities to provinces and replaces Home–Post with Home interacted with each quarter:

$$\begin{aligned}\text{LGFV bond share}_{apq} = &\sum_{k \neq q_0} \eta_k \, \mathbb{1}\{\text{Home buyer}\}_{ap} \mathbb{1}\{q = k\} \\ &+ \mu_{ap} + \mu_{aq} + \mu_{pq} + u_{apq},\end{aligned} \qquad q_0 = 2023\text{Q2}. \tag{D.6}$$

Province p is the investment destination. Its LGFV bonds are measured as a percentage of the buyer's total bonds. As in the city design, Home equals one only for a local bank investing in its headquarters province. National banks remain in the comparison group. Buyer–province, buyer–quarter, and destination-province–quarter effects are the provincial counterparts of the city design. Each η_k is the change in the home–outside allocation gap since 2023Q2, not a holding level. The sample is 2022Q1–2025Q3, outcomes are winsorized at the 1st and 99th percentiles, and errors cluster by bank city. Home levels and time-varying bank/province controls are absorbed. Pre-announcement confidence intervals include zero. The relative home allocation falls by about 2.3 percentage points in 2024Q1, 4.2 by 2024Q4, and 6.1 by 2025Q3. These province-wide changes differ from the per-city estimates in Table 6.

The maturity-wall test examines whether home banks provide additional financing when local borrowers have more principal due. In Table A8, the allocation specification is

$$\begin{aligned}\text{Outcome}_{acq} = &\beta \, \mathbb{1}\{\text{Home buyer}\}_{ac} \times \text{Maturity wall}_{cq} \\ &+ \mu_{ac} + \mu_{aq} + \mu_{cq} + \varepsilon_{acq}.\end{aligned} \tag{D.7}$$

The buyer, city, and quarter indices are the same as in equation (10). The wall varies by issuer city c and quarter q: it is principal on all LGFV bonds maturing there as a percentage of 2020 city budget revenue. Home identifies local banks investing in their own province. Bank-by-city, bank-by-quarter, and issuer-city-by-quarter effects absorb persistent ties, common funding conditions, and destination shocks. Each buyer enters with every issuer city whose LGFV bonds it holds at some point in the sample, in every quarter in which it reports holdings, so quarters without activity in that city contribute zeros.

In Panel B of Table A8, we examine which bonds home banks add when maturities are high. For bond j newly appearing in buyer a's holdings in quarter q, the specification is

$$\begin{aligned}\text{Bond characteristic}_{jaq} = \beta_H \, \mathbb{1}\{\text{Home buyer}\}_{a,c(j)} \\ + \beta_W \, \mathbb{1}\{\text{Home buyer}\}_{a,c(j)} \times \text{Maturity wall}_{c(j),q} \\ + \mu_{aq} + \mu_{c(j),q} + \varepsilon_{jaq}.\end{aligned} \tag{D.8}$$

The function $c(j)$ gives the bond issuer's city. Each regression uses one purchased-bond characteristic as its outcome: issuer rating, guarantee status, maturity, issue spread, or log issue amount. The Home level is included because buyer–city effects are absent, and the Wall level is absorbed by issuer-city-by-quarter effects. The coefficient β_W asks whether the home–outside difference in that characteristic changes with scheduled maturities. Both panels use bank-city clustered errors and the same unstandardized percentage-point wall measure.

The home–wall coefficients are -0.00696 for net buying and 0.00446 for exits. Both outcomes are percentages of the buyer's previous-quarter bond holdings. A ten-percentage-point larger wall therefore predicts about 0.070 points less net buying and 0.045 points more exits by home banks relative to other buyers of the same city's bonds.

Among new purchases, the guarantee-indicator interaction is 0.00116 per percentage point of the wall. A ten-point larger wall thus widens the home–other buyer gap in guarantee probability by 1.16 percentage points. The issuer-rating interaction is also positive. Home banks reduce net financing and seek more protection as repayments come due, so their support for local borrowers is selective.

D.5. Product assets and net flows

The demand tests distinguish money entering a product from growth generated by its investments. We infer product assets as 100 times the median ratio of a disclosed position's value to its percentage weight. Net flow then removes investment returns from asset growth:

$$\text{Net flow}_{iq} = 100 \frac{AUM_{iq} - AUM_{i,q-1}(1 + R_{iq})}{AUM_{i,q-1}}, \tag{D.9}$$

where AUM_{iq} is product i's inferred assets at the end of quarter q and R_{iq} is the simple quarterly return expressed as a fraction. A value of five means net inflows equal 5% of beginning assets. We apply the baseline 1st–99th percentile exclusion to monthly log returns before compounding, require three consecutive monthly returns per share class, and average class-level quarterly returns within each product. Both assets and returns must be observed at the required consecutive quarter ends. Flow tails are capped at the global 1st and 99th percentiles before selecting complete regression observations. These disclosure-based flows

capture net investor transactions among continuing observed products. Redemptions from products that disappear from the holdings data are outside this sample.

The ranking comparison in Table A9 uses equation (5) in the main text. Products are ranked within their prior risk-rating and redemption category $g(i, q-1)$, with category-by-outcome-quarter effects. Peer sets include national and local banks, require at least 20 products and three underlying banks, and are formed before selecting on subsequent flow availability. Tied returns receive midranks. Column 2 also absorbs home-province-by-outcome-quarter effects. These are cross-bank comparisons without bank effects.

The eleven control variables are log product assets, risk, redemption, log bank assets, nonperforming-loan ratio, cost-to-income ratio, net interest margin, and home-city GDP, GDP growth, LGFV debt/GDP, and urban income. We also include a local-bank indicator. Product assets are measured at the beginning of the flow quarter, and the remaining controls in the preceding quarter. Risk and redemption levels are absorbed by the category effects. Standard errors are clustered by underlying bank, labeled parent bank in the tables, combining a bank and its wealth-management subsidiary. The outcome sample covers 2022Q3–2025Q3, and earlier observations supply lags.

Alternative outcomes test whether a few unusually large flow rates drive the ranking result. Write $\widehat{A}_{iq} = AUM_{i,q-1}(1+R_{iq})$. Symmetric flow is $200(AUM_{iq} - \widehat{A}_{iq})/(AUM_{iq} + \widehat{A}_{iq})$, bounded between -200 and 200 without tail capping. Positive flow is $100\,\mathbb{1}\{AUM_{iq} > \widehat{A}_{iq}\}$, so its coefficient is a percentage-point difference in the probability of net inflows.

A linear benchmark replaces the quintile indicators with the previous quarter's return in percentage points, retaining the controls and category-by-quarter effects. Its coefficient is 9.381 (SE 2.064, 123,804 observations): ten basis points more quarterly return predicts next-quarter inflows higher by 0.94% of beginning assets. The ranking comparison spans a larger return difference, averaging 1.275% in the top fifth versus 0.246% in the bottom fifth. Both designs use the same return construction and lagged controls, with samples determined by their respective data requirements.

D.6. Full-period returns and downside outcomes

The return premium describes average reported performance. To assess what savers observed beyond that average, Table A7 also examines volatility and downside outcomes. Its full-period specification is

$$\begin{aligned}\text{Outcome}_{im} = \beta\,\text{Portfolio home overweight}^{LGFV}_{i,h(m)} + \gamma'\,\text{Controls}_{i,h(m)} \\ + \lambda\,\mathbb{1}\{\text{Local bank}\}_b + \alpha_m + \varepsilon_{im}.\end{aligned} \tag{D.10}$$

The dependent variable Outcome_{im} is monthly NAV return or one of the reported volatility and downside measures. Here i indexes a separately priced NAV series, as in equation (4). The exposure $\text{Portfolio home overweight}^{LGFV}$ is the home LGFV bond share of included holdings

minus the corresponding provincial benchmark, measured as a fraction at the preceding quarter end. The eleven baseline controls, a local-bank indicator, and month effects enter, and errors cluster by bank-city-by-month cells. Returns are consecutive-month changes in log adjusted NAV, and trailing annualized volatility uses the twelve-month window ending in the current month, with at least two available returns. In Panel B, excess return subtracts the mean return of products with the same redemption type, downside volatility uses only negative monthly returns, and drawdown is 100 times the trailing-peak log NAV minus the current log NAV. The remaining outcomes are indicators for a negative monthly return, a bottom-decile monthly return, and a drop of more than 50 basis points.

Section 3.3 reports the estimates. They are associations in reported NAVs, conditional on bank type and the other controls, and describe the full-period experience of the local-bond strategy. Table 3 separately estimates how its return premium changes after the program.

D.7. Pricing, distress, and sample timing

The purchase-share comparisons in Tables A11 and A12 use equation (6) in Section 3.5. Bond j is observed in its issue quarter q, and $c(j)$ identifies its issuer city. The pricing outcome is the CSI valuation spread at listing minus the issue spread, in basis points, with both spreads measured relative to Treasury yields at the corresponding date. The distress outcome is the subsequent issuer-distress indicator scaled to 100. Both purchase shares divide WMP holdings first disclosed in the issue quarter by the bond's total issued amount and multiply by 100. Same-city buyers are WMPs of banks headquartered in the issuer's city, and other-city buyers are WMPs of banks elsewhere in the same province. These holdings proxy for primary-market purchases, rather than identifying order-level allocations. The main specification includes issuer-city-by-issue-quarter effects, and the tables also report comparisons with issue-quarter or issuer-province-by-quarter effects in their place. The contrast $\beta_C - \beta_P$ measures the association of shifting one point of the purchase share from other-city provincial banks to same-city banks, holding their combined share fixed. Bond and ownership controls are listed in the tables, and the distress regression adds the public valuation spread to compare issuers with similar observed ex ante risk.

The pricing sample ends in 2025Q3, the last quarter of holdings coverage. We exclude 977 otherwise eligible LGFV issues in 2025Q4 rather than treating unobserved ownership as zero. The common LGFV sample has 21,116 issues, with 20,526 remaining after removing singleton city-quarter cells. Clustering by issuer gives a standard error of 0.355 for the 1.01-basis-point contrast in column 4 of Table A11 ($p = 0.0044$). The non-LGFV contrast in column 5 is small and imprecise, so the pricing difference between the two local ownership groups is concentrated in LGFV bonds, where local public-financing relationships are most relevant.

D.8. The scale of the WMP–LGFV bond link

A bond-only denominator gives a simpler benchmark for the LGFV shares in Section 3.1. We sum reported LGFV bond values and divide by the reported value of all positions identified as standard bonds within each bank group over 2022Q1–2023Q3, retaining government and policy-bank bonds and excluding private credit. Using valid product identifiers and the current underlying-bank classification gives 38.5% for local banks and 13.2% for national banks. This broader sample contains 46,772 local-bank and 45,346 national-bank product-quarters. By contrast, Table D1 uses matched product-quarters with positive included debt holdings: 36,194 and 34,595, respectively. Within that matched local-bank sample, LGFV bonds account for 40.4% of identified standard-bond value, 47.5% after restricting the denominator to eligible standard bonds (those in included debt holdings), and 43.1% after adding eligible private credit. The bond-only and debt-allocation shares therefore measure different portfolios.

For market context, we reconstruct the year-end 2021–2024 top-ten holdings cross-sections from the original Wind exports. We retain one representative record per product registration code and deduplicate positions within that record, preserving identical investments made by distinct products. We restrict amounts to yuan-denominated positions, identify bonds by asset type, and match issuers to the January 4, 2026 LGFV roster. Unidentified bond issuers remain in the denominator but not the LGFV numerator. In 2024, the retained disclosures contain RMB 0.3859 trillion of LGFV bonds out of RMB 2.3459 trillion of bonds, including negotiable certificates of deposit: a ratio of sums of 16.45%, not an equally weighted average of product ratios.

For each year t, let q_t be this disclosed LGFV-to-bond ratio, B_t the industry's bond assets including negotiable certificates of deposit, and A_t its net assets under management, from the annual WMP market reports. Estimated LGFV bond holdings are $\widehat{H}_t = B_t q_t$, and their share of WMP assets is $\widehat{H}_t/A_t$. The annual WMP market report published in 2025 gives year-end 2024 values of $B_t = 18.60$ and $A_t = 29.95$ trillion yuan. Using unrounded holdings gives $\widehat{H}_t = 3.06$ trillion yuan, or 10.2% of net assets under management. Equivalently, the rounded inputs give $16.45\% \times (18.60/29.95) = 10.22\%$. The extrapolation applies the disclosed bond mix to the industry's bond assets. It excludes private credit and indirect exposure through funds and other investment vehicles.

This total-asset benchmark is not a weighted average of the 43.1% and 12.6% in Table D1, which are pre-program shares of included debt holdings. On a common date and sample, LGFV/AUM = (LGFV/Debt) × (Debt/AUM), where Debt is the value of included debt holdings, and total WMP assets also include deposits, funds, central-government and policy-bank securities, and other assets.

The reverse ratio is $\widehat{H}_t/O_t$, where O_t is the published year-end LGFV bond balance. Lianhe Ratings (2024) reports Wind balances of RMB 9.81, 10.62, and 11.48 trillion for

2021–2023. Zhang (2025) reports RMB 10.88 trillion for 2024, implying a 28.1% benchmark holding share that year. Figure A4 leaves the 2024 reverse-ratio point unconnected to mark the change in source. These ratios describe two different economic exposures. Under the extrapolation, LGFV bonds account for about one-tenth of WMP assets in 2024, but WMPs hold more than a quarter of the LGFV bond market. A portfolio allocation within a large savings industry can therefore be an important financing source for the borrowers, even though local bonds do not dominate the industry's total assets.

D.9. Initial credit specialization and subsequent substitution

The allocation tests compare initial portfolios across all banks and the subsequent expansion of private credit within local banks. Table D1 describes the initial portfolios, Table 1 estimates the all-bank size relationship, and Table D2 tests its subsequent change within local banks. Table D3 compares the largest tenth with the remaining local banks.

The initial comparison estimates equation (1) on national- and local-bank product-quarters over 2022Q1–2023Q3. Outcomes are percentage-point shares of included debt holdings, retaining products with zero holdings in a class. The fixed size measure Log bank size$_b$ is log FY2021 interest-bearing assets in RMB trillion and replaces contemporaneous assets, with the other ten covariates grouped as Controls. Quarter effects remove common movements. The regression weights by the value of included holdings and clusters by parent bank. It does not include a national-bank indicator, so the size coefficient captures differences both across bank types and within them. Across this market, larger banks hold less in LGFV bonds, mainly home bonds, and more in private credit overall. The relationship with home private credit is much smaller because national banks hold most of their private credit outside their headquarters provinces.

We use two ratios that answer different questions. The first measures geographic concentration within an asset class. Product i is observed in quarter q, j indexes its disclosed positions, and n labels the asset class. Let w_{ijq} be the position's holding weight, p_b the underlying bank's home province, p_j the borrower's province, and $\mathcal{C}_{iq}^n$ the product's positions in class n. Then

$$\text{Home share}_{iq}^n = \frac{\sum_{j \in \mathcal{C}_{iq}^n} w_{ijq} \mathbb{1}\{p_j = p_b\}}{\sum_{j \in \mathcal{C}_{iq}^n} w_{ijq}}, \tag{D.11}$$

is the class's home share. Within-category home bias is its deviation from the market-portfolio weight:

$$\text{Within-category home bias}_{iq}^n = \text{Home share}_{iq}^n - \text{Province share}_{p_b,q}^n.$$

Here Province share$_{p_b,q}^n$ is the fraction of nationwide disclosed class-n holdings invested in borrowers in the bank's home province. Both the product ratio and the benchmark use class-n holdings alone as their denominator. Zero within-category home bias means investing

at market weights within that class. The measure uses products with positive holdings in the class.

The second ratio measures the share of all included debt holdings invested in each home asset class:

$$\text{Home allocation}_{iq}^{n} = \frac{\sum_{j \in \mathcal{C}_{iq}^{n}} w_{ijq} \mathbb{1}\{p_j = p_b\}}{\sum_{j \in \mathcal{C}_{iq}} w_{ijq}}, \tag{D.12}$$
$$\text{Portfolio home overweight}_{iq}^{n} = \text{Home allocation}_{iq}^{n} - \text{Province allocation}_{p_b,q}^{n}.$$

Here $\mathcal{C}_{iq}$ pools the included debt holdings, and $\text{Province allocation}_{pq}^{n}$ is the fraction of nationwide holdings across these classes invested in class n from borrowers in province p. Thus the product ratio and its benchmark both use the broader debt denominator, rather than class n alone. A raw $\text{Home allocation}^{n} = 0.20$ means RMB 20 in that home asset class per RMB 100 of included debt holdings. Products with no holdings in the class have zero raw allocation and remain in the sample before the benchmark is subtracted. Within-category home bias^{n} measures where a product invests in an asset class, whereas $\text{Portfolio home overweight}^{n}$ also reflects how much it invests in that class. The total Portfolio home overweight sums across classes. Combined home exposure, used in Table A13, includes home LGFV bonds and home PC but not home other bonds.

To examine subsequent adjustment without imposing size-group boundaries, Table D2 estimates

$$\begin{aligned}\text{Private credit share}_{iq} = {} & \beta_S \,\text{Log bank size}_b + \delta_S \,\text{Log bank size}_b \times \mathbb{1}\{\text{Post}\}_q \\ & + \gamma' \,\text{Controls}_{iq} + \alpha_q + u_{iq}.\end{aligned} \tag{D.13}$$

The outcome is local-bank product i's total or home private credit as a percentage of its included debt holdings in quarter q. Size is log FY2021 underlying-bank interest-bearing assets in RMB trillion, without standardization, and Post begins in 2023Q4. The ten controls are those in equation (1). Quarter effects absorb common movements and the Post level. The sample covers 2022Q1–2025Q3, with holding-value weights and underlying-bank clustered errors. The coefficient β_S measures the pre-program size slope, δ_S its subsequent change, and their sum the post-program slope. Bank-effect versions absorb fixed size and retain contemporaneous bank assets as an additional control.

The home private credit slope rises from 4.72 to 12.18 percentage points per log point of bank assets. The 7.47-point increase implies about 5.2 percentage points more expansion at a bank twice as large. Columns 3–4 add bank fixed effects to compare changes within banks. The size–Post interaction remains positive, and bank wild-bootstrap inference rejects a zero interaction in all four columns.

Table D3 compares the local banks in the top tenth of FY2021 interest-bearing assets with the remaining banks in the regression sample. It replaces the two group–Post interactions in

equation (11) with a top-tenth indicator interacted with Post, retaining bank and quarter effects and the same controls. The estimated difference in home private credit shares is 14.29 percentage points with investment-value weights and 9.49 points with equal bank-quarter weights.

The next comparison separates bank size from initial home orientation. Banks already investing more at home may respond differently to the loss of local bond yield. Table 9 allows both characteristics to predict adjustment as refinancing proceeds:

$$\begin{aligned}\text{Private credit share}_{iq} = {} & \beta_S \,\text{Log bank size}_b \times \text{Refinancing}^{debt}_{p_b,q} \\ & + \beta_B \,\text{Initial home overweight}_a \times \text{Refinancing}^{debt}_{p_b,q} \\ & + \gamma' \,\text{Controls}_{iq} + \alpha_a + \alpha_{p_b,q} + \varepsilon_{iq}.\end{aligned} \tag{D.14}$$

The outcome is the product's home or non-home private credit share, in percentage points. Initial home overweight is the institution's pre-program investment at home above provincial market weights across bonds and private credit (Section 4.4). Refinancing is cumulative special-refinancing issuance divided by 2020 LGFV debt in the bank's home province, not the borrower's province. Institution effects absorb persistent allocation differences and both initial-characteristic levels. Home-province–quarter effects absorb shared regional conditions, including the refinancing level. The eleven time-varying controls enter, observations are holding-value weighted, and errors cluster by bank city–quarter. A positive β_S means that larger banks expand more as refinancing increases, conditional on initial home orientation. Panel B replaces refinancing with Post in both interactions, leaving the other terms unchanged.

In Panel A, a ten-percentage-point increase in refinancing relative to initial provincial LGFV debt is associated with about 1.7 percentage points more home private credit expansion at a bank twice as large. Panel B gives 4.1 points more expansion after implementation. The raw coefficients are 24.21 and 5.85, respectively, and the comparisons are $24.21 \times 0.10 \times \ln 2 = 1.68$ and $5.85 \times \ln 2 = 4.06$ percentage points. Thus larger banks expand more even within provincial markets and conditional on their initial home investment.

Table D1
Initial credit portfolios by bank type and bank size

Share (%)	All provinces		Home province	
	LGFV bonds	PC	LGFV bonds	PC
Panel A. Bank type: all available banks				
National banks	12.6	24.1	0.4	2.1
Local banks	43.1	9.3	24.7	6.1
Panel B. FY2021 size terciles: local banks present in both periods				
Smallest tercile	38.6	1.1	25.1	0.7
Middle tercile	53.3	5.3	37.7	3.5
Largest tercile	40.6	11.4	20.7	7.4

Notes: PC denotes private credit. This table documents the initial allocation levels underlying the all-bank and local-bank size comparisons. Entries are percent of included debt holdings, not all standard bonds or total WMP assets, value weighted, over 2022Q1–2023Q3. All-province shares include home and non-home positions, and home means the parent bank's headquarters province. The denominator excludes deposits, funds, other investment vehicles, and central-government, central-bank, and policy-bank obligations. Panel A contains 34,595 national-bank and 36,194 local-bank product-quarters. Panel B uses the same local banks and fixed FY2021 interest-bearing-asset terciles as Panel C of Table 7, contributing 1,965, 9,617, and 22,911 pre-period product-quarters. No class-specific positive-holding condition is imposed. Table 1 reports controlled comparisons on complete-case samples. Before implementation, local banks hold 65.0% of the sample's LGFV bonds and national banks hold 82.7% of its PC. After implementation, the corresponding fractions are 62.6% and 68.7%. Ending the initial comparison before the July announcement gives the same descriptive sorting: local and national LGFV shares are 42.4% and 12.2%, while PC shares are 9.5% and 24.0%.

Table D2
Larger local banks and the expansion into private credit

Dependent variable	Total PC share (pp) (1)	Home PC share (pp) (2)	Total PC share (pp) (3)	Home PC share (pp) (4)
Log bank size	7.382*** (2.542)	4.716*** (1.757)	*Absorbed*	*Absorbed*

Implied contrast from the same regression				
Post-program size gradient	17.535*** (3.300)	12.185*** (2.509)	—	—
Wild p: log bank size × Post	< 0.001	< 0.001	< 0.001	0.017
Observations	85,182	85,182	85,181	85,181
Quarter fixed effects	Yes	Yes	Yes	Yes
Parent bank fixed effects	No	No	Yes	Yes
Standard errors	Parent bank	Parent bank	Parent bank	Parent bank

Notes: Each column is one local-bank regression of total or home private credit (PC) as a percentage of included debt holdings, with quarter effects, the displayed controls, and holdings weights. Size is unstandardized log FY2021 parent-bank interest-bearing assets in RMB trillion. Post begins in 2023Q4 and its level is absorbed by quarter effects. Columns 1–2 estimate the initial size slope and its change, and the post slope sums them, with its standard error from their covariance. Columns 3–4 add bank effects, absorb fixed size, and retain current bank assets. Parentheses contain parent-bank clustered errors, and wild tests use 4,999 Rademacher draws. Stars indicate 10%, 5%, and 1% significance. Appendix D.9 provides details. Estimation sample: 2022Q1–2025Q3.

Table D3
Private-credit allocation at the largest local banks

Dependent variable	Home private credit share (pp)	
Weighting	Investment value	Equal bank-quarter
	(1)	(2)
Largest tenth × Post	14.291***	9.486**
	(3.721)	(3.713)
Product, bank, and city controls	Yes	Yes
Observations	85,181	85,181
Bank fixed effects	Yes	Yes
Quarter fixed effects	Yes	Yes
Standard errors	Parent bank	Parent bank

Notes: Each column is a separate local-bank product-quarter regression. Bank effects absorb the fixed top-tenth indicator, and quarter effects absorb Post. Largest tenth identifies the top tenth of banks in the Table 8 sample, ranked by FY2021 interest-bearing assets. Post begins in 2023Q4. Both columns include the controls in Table 8. Investment-value weights use included debt value. Equal-bank-quarter weights sum to one within each bank-quarter and weight its products by their disclosed investment value. Parentheses contain bank-clustered standard errors, and stars denote 10%, 5%, and 1% significance. Sample: 2022Q1–2025Q3.

Table D4
The private credit–bond rate gap within the same borrower: alternative comparisons

Dependent variable: contractual borrowing yield (percent).

Specification	Baseline	Debt-specific maturity	Equal cell weights	2023Q2 borrowers
	(1)	(2)	(3)	(4)
$\mathbb{1}\{\text{Private credit}\}$ (2023Q2 gap)	1.904***	1.749***	1.789***	1.848***
	(0.101)	(0.102)	(0.114)	(0.107)
$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Quarter} = 2023Q1\}$	−0.676***	−0.700***	−0.665***	−0.528***
	(0.115)	(0.104)	(0.132)	(0.131)
$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Quarter} = 2024Q4\}$	0.955***	1.060***	1.337***	0.681**
	(0.214)	(0.248)	(0.204)	(0.303)
$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Quarter} = 2025Q3\}$	1.057***	1.197***	1.067***	1.107**
	(0.218)	(0.217)	(0.239)	(0.502)
Observations	17,303	17,303	17,303	8,088
Quarter-specific maturity controls	Yes	Debt-specific	Yes	Yes
Borrower × calendar month fixed effects	Yes	Yes	Yes	Yes
Standard errors	Borrower province	Borrower province	Borrower province	Borrower province

Notes: Each column is one regression. Same borrower means that private credit and bonds are matched to the same legal borrower, and affiliates are excluded. The first row is the private-credit main effect when the quarterly coefficients are expressed relative to 2023Q2. Subsequent rows are changes from that gap. Column 2 evaluates the gap at three years, column 3 gives borrower-quarter-debt-type cells equal weight, and column 4 retains the 101 borrowers with both channels in 2023Q2 and later matched financing. Only key contrasts are tabulated. Parentheses contain province-clustered standard errors, and stars use t_{G-1} tests at 10%, 5%, and 1%, where G is the number of province clusters. The full baseline path is in Figure 3, and Appendix D.2 details matching, singleton removal, and coverage. Estimation sample: 2021Q1–2025Q3.

Table D5
Inference for the same-borrower rate gap

Panel A. Selected regression contrasts and inference

Dependent variable	Contractual yield (pp) (1)	Borrower-month PC–bond gap (pp) (2)
$\mathbb{1}\{\text{Private credit}\}$ (2023Q2 gap)	1.904*** (0.101)	—
$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Quarter} = 2024Q4\}$	0.955*** (0.214)	—
$\mathbb{1}\{\text{Quarter} = 2024Q4\}$	*Absorbed*	1.182*** (0.245)
$\mathbb{1}\{\text{Private credit}\} \times \mathbb{1}\{\text{Quarter} = 2025Q3\}$	1.057*** (0.218)	—
$\mathbb{1}\{\text{Quarter} = 2025Q3\}$	*Absorbed*	1.009*** (0.217)
Inference for the corresponding quarter contrast		
2024Q4: 95% province wild-bootstrap set	[0.472, 1.676]	[0.699, 1.899]
2025Q3: 95% province wild-bootstrap set	[0.440, 1.883]	[0.414, 1.761]
2024Q4: Province wild-bootstrap p	0.0039	0.0017
2025Q3: Province wild-bootstrap p	0.0056	0.0039
Observations	17,303	2,525
Quarter-specific maturity controls	Contract maturity	Maturity difference
Borrower × calendar month fixed effects	Yes	No
Standard errors	Borrower province	Borrower province

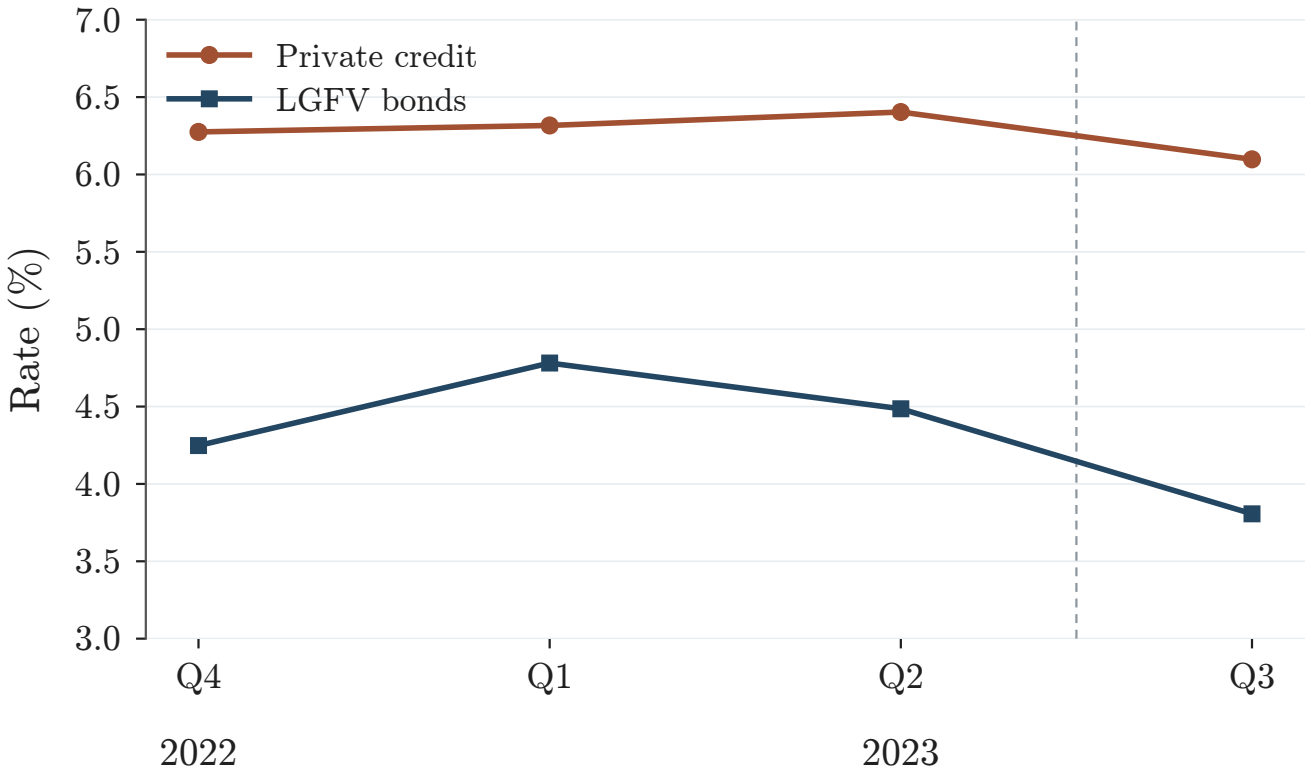

Panel B. Financing coverage (descriptive)

Coverage	2024Q4	2025Q3
PC contracts	360	81
Bond issues	140	40
Borrowers	75	21
Borrowers with both channels in a month	58	19
Provinces	13	9
Borrower-months with both channels	68	24

Notes: PC denotes private credit. Column 1 uses the contract-level model of Table D4, and column 2 regresses one borrower-month PC-minus-bond gap on quarter indicators and quarter-specific maturity differences, with no borrower effect. The first row reports the yield gap in the reference quarter, 2023Q2. The other coefficient rows are changes from that gap, in annual percentage points. In column 1 the reference gap is the private-credit main effect, and borrower-by-month effects absorb quarter indicators. Column 2 already takes the PC-minus-bond difference, so no separate private-credit indicator enters. Parentheses contain province-clustered errors. Confidence sets invert null-imposed bootstrap-t tests with 9,999 Webb-weight province draws. All quarterly terms remain estimated. Panel B reports financing coverage in the two quarters of Panel A. Appendix D.2 reports the leave-one-province estimates. Stars indicate 10%, 5%, and 1% significance. The two regression samples contain 26 and 25 borrower-province clusters, respectively.

Figure D1

Contractual rates for a fixed set of borrowers

Notes: Annual contractual yields on private credit (PC) and bonds for the same 22 legal borrowers in every quarter from 2022Q4 through 2023Q3, using 799 financing records in seven provinces. Each borrower has both channels in at least one common calendar month of every quarter. Within each borrower-month, contracts or bond issues receive equal weight within their channel. Matched monthly means are averaged within borrower-quarter using $h = n_{PC}n_B/(n_{PC} + n_B)$, where n_{PC} and n_B count records in the two channels, and the same weights apply to both series. Each borrower then receives weight 1/22 in each quarter. These are observed uncapped contractual rates, without regression or seasonal adjustment. Borrowers and their quarterly weights are fixed, but contracts and maturities can change. The shorter diagnostic window is required by common-borrower coverage and differs from the full sample in Figure 3. Internet Appendix D.2 discusses the Q1–Q2 comparison.

Internet Appendix E
Return, Balance, and Mechanism Checks

This appendix first checks return measurement (Table E1 and Table E2), then balance reporting (E.1) and holdings disclosure (E.2). It then examines return losses by initial home LGFV exposure (E.3), relates private-credit expansion to returns (E.4), and explains the measurement of balances in newly launched WMPs (E.5).

In Panel A of Table E1, we ask whether bond income explains part of the disappearing home LGFV return premium. On identical observations, we add the portfolio's holdings-weighted original bond issue yield and its Post interaction to the return model. The home LGFV Post coefficient changes from −6.33 to −2.57 monthly basis points per unit share. For a 20-point allocation difference, the annual loss falls from about 15 to 6 basis points. The attenuation is consistent with lower bond income contributing to the loss of the home LGFV return premium. The post-program private credit premium remains positive.

The remaining columns require issue rates for at least half of included debt holdings, keep products at least four quarters old with age and remaining-maturity controls, add trailing volatility and its Post interaction, average NAV-series returns within product-month, or restore observations removed by trimming. The volatility check requires nine observed monthly returns in the trailing twelve months. Each preserves the negative LGFV premium change and positive post-program private credit premium. Across the untrimmed column and three further untabulated treatments of extreme returns, the home LGFV Post coefficient ranges from −6.03 to −6.61 and the post-program private credit premium from 3.96 to 4.64 monthly basis points per unit share.

In Table E2, we ask whether the result survives differences in when NAVs recognize gains and losses. Complete six- and twelve-month windows retain annualized home LGFV premium losses of about 16 and 13 basis points for a 20-point exposure difference, alongside post-program home private credit premiums of 13 and 12 basis points (columns 2 and 4). The raw-return columns and the existing-product columns, which keep products observed both before and after the program, show the same pattern for home LGFV bonds, whose post-program premium is close to zero.

We also check the home classification. Table 3 never counts centrally administered issuers as home. Counting those in the bank's province as home changes other-bond shares in 27,244 product-quarters and private credit shares in 328, and leaves home LGFV shares unchanged (estimates not tabulated). The home LGFV level and Post coefficients become 8.31 and −5.32, versus 8.85 and −6.13 in the primary model. The non-home LGFV level is 2.29, with home–non-home equality rejected at $p < 0.001$.

The complete-window specification measures performance over $H = 6$ or 12 months and retains the asset shares and controls in equation (4):

$$\begin{aligned}\text{Window return}_{iw}^{(H)} = {} & \beta_H' \,\text{Asset shares}_{i,h(w)} \\ & + \delta_H' \,\text{Asset shares}_{i,h(w)} \times \mathbb{1}\{\text{Post}\}_w \\ & + \gamma_H' \,\text{Controls}_{i,h(w)} + \lambda_H \,\mathbb{1}\{\text{Local bank}\}_b + \alpha_w + \varepsilon_{iw}.\end{aligned} \tag{E.1}$$

Here w is the first month of the return window and $h(w)$ the preceding quarter, using the same lag convention as the monthly model. For each NAV series, we sum all H monthly log returns in basis points and divide by H. We then average complete series within product to obtain Window return$_{iw}^{(H)}$. Exposure shares and the eleven controls are fixed at the quarter end before the window, and α_w absorbs common window-date conditions. Coefficients are estimated separately for each horizon. Thus δ_H measures the change in an exposure's premium in average monthly basis points, the units of the monthly model, and does not cumulate returns over the H months. Table E2 gives the transition exclusions and April–March comparison dates. Errors cluster by underlying bank.

E.1. Coverage and interpretation of bank-level WMP balances

We ask whether smaller banks' weaker WMP growth reflects changing reporting coverage or the different organizational forms of large and small banks. The specification is equation (15) in the main text.

The balance panel uses source-verified corrections to the Wind entries. Yuhang Rural Commercial Bank's June 2025 balance is RMB 16.909 billion.[51] Ruifeng's December 2022, 2023, and 2024 balances are RMB 14.247, 12.797, and 9.582 billion, and Fudian's December 2022 and 2023 balances are RMB 21.154 and 21.450 billion. These replace Wind entries that were roughly twice the reported totals.[52] All balance regressions and the balance event study use this corrected panel. Missing reports remain missing, and verified contractions are retained.

We classify a bank as having a pre-program subsidiary if we observe a product registered to that subsidiary by 2023Q2. The definition uses observed products rather than licensing dates. To compare banks within organizational form, we replace common half-year effects with separate half-year effects for banks with and without subsidiaries. A further specification allows a different size–Post coefficient in each group. Both retain bank effects and bank-clustered inference.

[51] The bank's first-half 2025 report, Table 3, gives 169.09 hundred-million yuan and 191 products, and its year-end report confirms the June amount. The Wind entry was 0.0169.

[52] Ruifeng's 2022 annual report and 2024 annual report, including its 2023 comparative, verify these amounts. Fudian's 2022 annual report and 2023 WMP report verify its totals. The latter reports the same balance under two classifications, so the two totals should not be added.

The number of reporting banks rises through 2024H2 and falls in 2025H2. In Table E3, we address changing composition by excluding the final period, retaining only banks observed at every date, and excluding banks with pre-existing subsidiary products. The size-related growth difference remains positive in each sample. Allowing subsidiary banks either a separate Post shift or their own half-year effects gives a coefficient of 0.105 log balance points per log point of assets (SE 0.040–0.041), implying about 7.5% greater relative growth for a doubling of size. With subsidiary-status-by-half-year effects, the wild p-value is 0.003.

Separate size–Post slopes are 0.099 for banks without pre-existing subsidiary products (SE 0.042) and 0.237 for banks with them (SE 0.084). Requiring an observed pre-announcement portfolio leaves 494 bank-half-years. With group-specific time effects, the size coefficient is 0.096 (SE 0.034, wild $p = 0.012$). These comparisons hold subsidiary status fixed.

Splitting banks at RMB50 billion of June 2023 WMP balances, below which no bank had pre-program subsidiary products, preserves the size gradient in both groups (Table E3, Panel B). With bank and common half-year effects, the size–Post coefficients are 0.095 below the cutoff and 0.256 at or above it (wild $p = 0.026$ and 0.049), implying 6.8% and 19.4% greater relative growth for a doubling of parent-bank size.

E.2. Top-ten disclosure coverage

Top-ten holdings cover different fractions of product assets, so measured allocations could vary with disclosure as well as investment choice. Table E4 checks three headline results by controlling for disclosure coverage and measuring home holdings relative to total product assets rather than included debt holdings. No minimum coverage ratio or position count is required.

We re-estimate three headline coefficients with their original specifications. They are the initial log-size slope of home LGFV allocations across all banks (equation (1)), the log size–Post slope of home private credit within local banks (equation (D.13)), and the home LGFV share–Post interaction in monthly returns (equation (4)). Allocation regressions keep holding-value weights, return regressions are unweighted, and each baseline–adjusted pair uses identical observations.

For each product, coverage is the sum of all reported position weights, expressed as a fraction, so disclosed positions totaling 40% give a coverage of 0.40. Adjusted regressions add cubic polynomials in coverage and log product assets, the number of disclosed positions, and the interactions of all these terms with Post, which allows nonlinear relationships that may change after implementation. In return regressions, these measures come from the preceding quarter end. Terms already in the baseline enter only once.

Panel A retains shares of included debt holdings. The initial size coefficient changes from -5.458 to -5.706: a bank twice as large has a home LGFV share 3.8 versus 4.0 percentage points lower. The private credit size–Post coefficient changes from 7.469 to 6.766, implying

5.2 versus 4.7 points more expansion at a local bank twice as large. The home LGFV return interaction changes from −6.133 to −5.863 monthly basis points per unit share. For a 20-point allocation difference, the annual premium loss is therefore 14.7 versus 14.1 basis points. All three adjusted estimates remain significant at 1%.

Panel B instead measures home holdings by their reported weights in product assets. Its return regression includes all six disclosed debt categories (home and non-home LGFV bonds, other bonds, and private credit) and their Post interactions, with other assets as the reference. The three disclosure-adjusted coefficients are −2.683, 3.175, and −8.603, all significant at 1%. Both adjustments preserve the headline patterns without reconstructing undisclosed holdings.

E.3. Initial home LGFV reliance and return erosion

In Table E5, we test whether banks initially more exposed to home LGFV bonds experience larger subsequent return declines, conditional on size. Relative to equation (12), this comparison omits both private-credit interactions and replaces common month effects with pre-program subsidiary-status-by-month effects, retaining bank effects. We average NAV series within product-month and products within bank-month, giving each bank-month equal weight. Return observations come from the full monthly NAV sample of yuan-denominated series, retain a global 1st–99th percentile exclusion of monthly returns, and need no contemporaneous holdings match. Initial exposure is measured from pre-program holdings. By comparison, the return columns of Table 9 use equally weighted NAV-series-months matched to lagged product characteristics and control for broad initial home overweight. These designs measure initial bond-exposure losses and size-related product-return differences, respectively.

Two further checks are not tabulated. The home-exposure coefficient is −10.69 monthly basis points per unit share after adding pre-program non-home LGFV share–Post, and −11.07 with quarter-specific size slopes (both wild $p < 0.001$). The exposure result therefore persists when accounting for general LGFV reliance or allowing the size–return relationship to change by quarter.

E.4. Private-credit expansion and WMP returns

Larger local banks expanded private credit more. We use equation (12) to test whether banks making greater use of that substitute also preserved more return, conditional on their initial portfolios and size. All four bank characteristics enter jointly, interacted with Post: initial home LGFV share, subsequent home private-credit expansion, initial size, and initial home private-credit share. Column 2 of Table 12, Panel A includes the eight lagged controls. Column 1 omits them.

The outcome is the bank's average monthly WMP log return in basis points, constructed as in Table E5. Post begins in 2023Q4. Bank and common month effects absorb fixed bank characteristics and the common Post change. Standard errors cluster by underlying bank.

Within each bank-quarter, the home private credit share divides home private credit holding value by the value of included debt holdings. Thus products are value-weighted within a bank. We average these quarterly shares over 2022Q1–2023Q2 and over 2023Q4–2025Q3, then take the latter minus the former to obtain ΔHome PC share$_b$. Equal weighting across quarters prevents growth in the disclosed portfolio from mechanically giving later quarters more weight. Banks need at least two observed holdings quarters in each period, and missing holdings are not treated as zeros. Initial home LGFV and private-credit shares use holding-value aggregation over the pre-program window. Initial size remains raw log FY2021 interest-bearing assets.

E.5. Measuring balances in newly launched WMPs

In Table 12, Panel B, we use the total balances of observed products launched by the same underlying local bank in the same quarter as a proxy for fundraising through newly launched WMPs. For each product launched in quarter q, we use total assets at the end of quarter $q+1$, constructed from the holdings-based asset measure in Appendix D.5. The measurement window retains products aged 90–183 days. We sum these positive balances within each bank–launch quarter, which we call a cohort, and then take the log. The outcome therefore combines the number of products launched with their balances. It is neither a bank's total outstanding WMP balance nor net subscriptions. Missing products or cohorts are not assigned zero balances.

Equation (13) compares cohort totals before and after the program using initial home LGFV exposure, subsequent home private-credit expansion, bank size, and initial home private-credit exposure, all interacted with Post. Column 4 reports this full specification. Column 3 omits the expansion interaction. Expansion, the initial shares, and size are defined as in Appendix E.4. Launches cover 2022Q2–2025Q2, excluding 2023Q3, and Post begins with launches in 2023Q4.

Columns 3–4 include bank and launch-quarter effects and the eight prior-quarter bank and home-city controls displayed in the table. Each bank–launch quarter receives equal weight, and standard errors cluster by underlying bank. The control vector is the same as in the return comparison in column 2 of Table 12, Panel A. Each outcome uses its full eligible sample rather than only the banks that report both outcomes.

Column 4 drops six cohorts without enough post-program holdings to measure expansion. Re-estimating column 3 on column 4's sample gives reliance and size coefficients of -1.525 and 0.216, close to -1.556 and 0.224 in the full sample. Thus requiring expansion data does not drive the change in the coefficients.

Standard errors	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank

Notes: Each column is one regression with the full controls and asset shares of Table 3. Exposure levels and their Post interactions enter together, and window-date effects absorb Post. Only the home LGFV and home private credit (PC) estimates are displayed. Parentheses contain parent-bank clustered errors. All monthly returns in a window must be observed. Exposure and controls precede the window, and complete share-class windows are averaged within product. Winsorized returns are capped at the 1st and 99th percentiles. Existing-product columns use winsorized returns of products observed both before and after the program. Windows spanning July–September 2023 are excluded, and annual April–March windows compare 2022–2023 with 2024–2025. Post-program premiums sum the level and Post interaction from the same column, using their covariance. Stars indicate 10%, 5%, and 1% significance.

Panel B. Organizational composition and the WMP-balance cutoff

Specification	Subsidiary × time (1)	Separate size slopes (2)	Observed pre-program portfolio (3)	Banks in (5)–(6) (4)	Below RMB50bn (5)	At/above RMB50bn (6)
Log bank size × 𝟙{Post}	0.105**	—	0.096***	0.151***	0.095*	0.256***
	(0.041)		(0.034)	(0.040)	(0.049)	(0.075)
Log bank size × 𝟙{Post}: subsidiary parents	—	0.237***	—	—	—	—
		(0.084)				
Log bank size × 𝟙{Post}: other parents	—	0.099**	—	—	—	—
		(0.042)				
Wild p: log bank size × Post	0.003	—	0.012	< 0.001	0.026	0.049
Observations	571	571	494	496	349	147
Bank fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Half-year fixed effects	No	No	No	Yes	Yes	Yes
Subsidiary × time fixed effects	Yes	Yes	Yes	No	No	No
Standard errors	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank

Notes: The outcome is log observed WMP balances. Each column is one bank-half-year regression with the displayed regressors and stated fixed effects. Bank effects absorb initial size and group indicators, and half-year or group-by-half-year effects absorb Post. In the within-subsidiary-status comparison, group-by-half-year effects also absorb subsidiary status × Post. No additional bank or city controls enter. Errors cluster by bank. Size is unstandardized log FY2021 bank interest-bearing assets in RMB trillion. Banks with a subsidiary before the program have a product registered to their wealth-management subsidiary by 2023Q2. Panel B columns 1–3 give them and other banks separate half-year paths, column 2 estimates a size slope for each group, and column 3 keeps banks with an observed pre-announcement portfolio, for which subsidiary status is known. The same-bank sample keeps banks observed at every date. Panel B columns 4–6 fix groups using June 2023 WMP balances, with column 4 pooling the banks that columns 5–6 split at RMB50 billion. No bank below the cutoff has observed pre-program subsidiary products. The cutoff is defined on WMP balances rather than parent-bank assets, and it does not correspond to bank-specific regulatory caps. Missing balances are neither zeros nor assigned to a group. Wild tests use 4,999 bank-level Rademacher draws. Appendix E.1 explains definitions and the verified balance corrections. Stars use conventional 10%, 5%, and 1% tests.

Table E4
Disclosure coverage and exposure denominators

Panel A. Shares of included debt holdings

Dependent variable	Home LGFV share (pp)		Home PC share (pp)		Monthly return (bp)	
Specification	Baseline	Adjusted	Baseline	Adjusted	Baseline	Adjusted
	(1)	(2)	(3)	(4)	(5)	(6)
Log bank size	−5.458***	−5.706***	4.716***	2.655	—	—
	(1.123)	(1.065)	(1.757)	(1.746)		
Log bank size × 𝟙{Post}	—	—	7.469***	6.766***	—	—
			(2.203)	(1.419)		
Home LGFV bond share	—	—	—	—	8.852***	8.747***
					(1.856)	(1.765)
Home LGFV bond share × 𝟙{Post}	—	—	—	—	−6.133***	−5.863***
					(1.501)	(1.296)
Baseline controls	Yes	Yes	Yes	Yes	Yes	Yes
Disclosure controls	No	Yes	No	Yes	No	Yes
Observations	68,331	68,331	85,182	85,182	554,555	554,555
Quarter fixed effects	Yes	Yes	Yes	Yes	No	No
Month fixed effects	No	No	No	No	Yes	Yes
Standard errors	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank

Panel B. Reported weights in product assets

Dependent variable	Home LGFV share (pp)		Home PC share (pp)		Monthly return (bp)	
Specification	Baseline	Adjusted	Baseline	Adjusted	Baseline	Adjusted
	(1)	(2)	(3)	(4)	(5)	(6)
Log bank size	−2.863***	−2.683***	1.491	−0.106	—	—
	(0.703)	(0.656)	(0.944)	(0.974)		
Log bank size × 𝟙{Post}	—	—	3.451**	3.175***	—	—
			(1.428)	(0.983)		
Home LGFV bond share	—	—	—	—	17.533***	18.518***
					(2.964)	(2.909)
Home LGFV bond share × 𝟙{Post}	—	—	—	—	−8.097***	−8.603***
					(2.366)	(2.594)
Baseline controls	Yes	Yes	Yes	Yes	Yes	Yes
Disclosure controls	No	Yes	No	Yes	No	Yes
Observations	68,331	68,331	85,182	85,182	554,555	554,555
Quarter fixed effects	Yes	Yes	Yes	Yes	No	No
Month fixed effects	No	No	No	No	Yes	Yes
Standard errors	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank	Parent bank

Notes: Each column is one regression. Focal interactions and their estimated main effects are shown. Quarter or month effects absorb Post. Columns 1–2 use all banks before implementation, columns 3–4 use local banks before and after, and columns 5–6 use monthly returns. Baseline models follow equations (1), (D.13), and (4). Adjusted columns add the disclosure controls described in Appendix E.2. The ten allocation controls and eleven return controls are retained, as are all exposure levels and interactions. Size is log FY2021 bank assets. Coverage sums all disclosed position weights, unlike rate coverage in Table E1. Panel B uses reported product-asset weights, without imputing undisclosed positions. Its return model includes all six home/non-home debt shares and their Post interactions. Allocation weights and bank clustering are unchanged. Zero category holdings remain in the sample. Parentheses contain bank-clustered errors. Stars denote 10%, 5%, and 1% significance.

Table E5
Initial home LGFV exposure and WMP-return erosion

Dependent variable: bank-average monthly WMP return (bp).

	Full sample (1)	Province comparison (2)	Sample of (4) (3)	Add controls (4)
Initial home LGFV bond share × 𝟙{Post}	−10.963***	−12.639***	−10.301***	−10.528***
	(2.657)	(4.079)	(3.355)	(3.410)
Wild p: initial home LGFV share × Post	< 0.001	0.002	0.002	0.003
Initial log bank size × Post control	Yes	Yes	Yes	Yes
Lagged bank controls	No	No	No	Yes
Lagged home-city controls	No	No	No	Yes
Observations	2,821	2,821	2,006	2,006
Bank fixed effects	Yes	Yes	Yes	Yes
Subsidiary status × month effects	Yes	Yes	Yes	Yes
Home province × month effects	No	Yes	No	No
Standard errors	Parent bank	Parent bank	Parent bank	Parent bank

Notes: Each column uses monthly log returns (bp), July 2022–September 2025, excluding July–September 2023. Bank effects absorb the initial exposure and size levels, and subsidiary-status-by-month effects absorb Post. Exposure is the 2022Q1–2023Q2 home LGFV bond share of included debt holdings, not total WMP assets. For a ten-point exposure difference, multiply the coefficient by 0.10 and then by 12 to annualize. The table displays the exposure coefficients, and initial log bank size interacted with Post remains a control in every column. Initial size is log FY2021 bank interest-bearing assets. Column 4 also includes lagged bank assets, nonperforming loans, cost–income ratio, net interest margin, and home-city GDP, growth, LGFV debt/GDP, and income. Post begins October 2023, and controls lag one quarter. Subsidiary status indicates whether the bank had a wealth-management subsidiary before the program. Column 3 uses the sample of column 4 without its controls. Products are equally weighted within bank-months, as are bank-months in estimation. Parentheses show bank-clustered standard errors in monthly units, and wild tests use 4,999 draws. Stars denote 10%, 5%, and 1% significance.
